Meeting held on Monday, November 2nd, 1896.

DR. R. MESSEL IN THE CHAIR.

THE PRODUCTION OF INOCULATING MATERIALS ("NITRAGIN") FOR USE IN AGRICULTURE.

BY J. AUGUSTUS VOELCKER, PH.D.

"NITRAGIN" claims to be a powerful agent capable of containing, as represented in a small bottleful, enough fertilising matter, and that of the right kind, for inoculating half an acre of the particular crop the name of which is marked on the bottle, with the organisms which shall enable it to utilise for itself the nitrogen of the atmosphere, and not only ensure an abundant crop of the particular plant, but also cause the soil, by its enrichment in stored-up nitrogen, to produce an after-crop of a nitrogen-loving nature, without the expenditure upon it of the considerable sums which it is usual to spend in the form of nitrate of soda and other nitrogenous fertilisers. This, then, is the purport of the introduction, and it is for us to see on what grounds the claim rests, whether there is reasonable probability of its success, and how far its production as a branch of chemical industry in the future is likely to be warranted. So far, I should say, "Nitragin" is confined in its application to crops of a leguminous nature, for they alone, according to our present knowledge, have the power of assimilating, under proper conditions, the atmospheric nitrogen. But it needs no great stretch of imagination to look to a possible development of the principle of inoculation of other agricultural crops by the fitting media. Before describing the actual commercial production of the article and its use, it is necessary, for a right understanding, to review the position of our knowledge as regards the nitrogen question and its practical application to agricultural ends.

After the successive rise and abandonment of the "humus" theory of Thaer and the "mineral" theory of Liebig, the "nitrogen" theory of Lawes and Gilbert became the prominent one, and has survived to this day in practical experience, as showing that it is pre-eminently nitrogen that is needed by agricultural crops, and that which they, as a whole, have the most difficulty in providing for themselves in sufficiency. Moreover, the experiments of Lawes, Gilbert, and Pugh, in 1857, under the particular conditions of their carrying out, showed that none of our ordinary field crops, the leguminous ones included, were able to directly assimilate the nitrogen offered to them in the atmosphere, but depended for their nitrogen on the supply of it to them in the form of manures, or as soil-nitrogen. So far as cereal crops and all others, except leguminous ones, are concerned, this belief has not been controverted

by any subsequent discoveries or experiments. But in regard to leguminous crops there had long been a divergence between theory and practice, and though the full explanation could not be given until a later date, when the famous experiments of Hellriegel and Wilfarth established a new truth, there was in the growth of leguminous crops and their influence on subsequent corn crops a something not explainable satisfactorily by the "nitrogen" theory. While corn crops and root crops clearly required nitrogen to be supplied to them beyond what was available for them in the generality of soils, leaving the soil subsequently the poorer in these constituents, clover and other leguminous crops not only thrive perfectly well without the application of nitrogenous manures, but left the surface of the soil far richer in nitrogen than it was before; in fact, a leguminous crop practically supplied a nitrogenous manuring for an after corn crop. And yet, in the face of Lawes and Gilbert's experiments as to the inability of crops to assimilate free atmospheric nitrogen, there was not sufficient explanation for this enrichment of the soil. But to the practical farmer the fact was perfectly well known and acted upon, as instanced in the beneficial working of a rotation of crops in which clover holds a place. Suggestions were now and again thrown out that, after all, the atmosphere might have something to do with explaining the seeming anomaly, and, as long ago as 1868, the late Dr. Voelcker, when showing how nitrogenous organic matter was stored up in the soil during the growth of a clover crop, and how it increased with the increase of the root fibres, went so far as to express the opinion that in some way that had not yet been explained the atmosphere *did* play a part in this storing up of nitrogen in the soil.

But it was not until the several years of steady work and patient enquiry in which Hellriegel had been engaged, culminated in 1886 with the pronouncement which he and his colleague Wilfarth were then able to make, that the true explanation of the influence of leguminous plants was supplied, and that it was then definitely shown that certain leguminous crops at least—among which were all the common field crops of this order—did possess the power, under favourable conditions, of assimilating and utilising the free nitrogen of the atmosphere.

This power, Hellriegel proved, they possessed through the medium of minute organisms, or bacteria, which existed in certain swellings or "nodules," as they were termed, found on the roots of these leguminous plants. The free nitrogen of the atmosphere held in the soil could be fixed by the organisms in the nodules, and in this way could be explained the storing of nitrogen by these plants, and the enrichment of the soil by their decay.

It is not necessary here to go in detail into the various steps by which Hellriegel and Wilfarth arrived at their conclusions, but it may be well to set out the principal lines of the inquiry. It had already long been noticed that the rootlets of leguminous plants growing luxuriantly in an ordinary fertile soil, bore on them certain swellings (the "nodules" already referred to), but their nature had not been investigated, nor had their possible connection with the question of the assimilation of free nitrogen been even hinted at. Hellriegel and Wilfarth, however, were the first to work out this connection. Their experiments were conducted on ordinary field crops, but grown in small pots filled with sterilised sand and kept moist as required, by distilled water free from nitrogen. A series of pots were arranged for each of the principal families of field crops, graminæ (cereals), crucifere (swedes), leguminosæ (peas, vetches), &c., and each was supplied with nutritive solutions containing the necessary phosphoric acid, potash, lime, &c., for plant growth, but containing no nitrogen whatever. Next, while to some of the pots in each series nothing else was added, to others a certain quantity of nitrogen in the form of a solution of nitrate of soda was added, to others double the amount, and so on. In the case of plants of the graminæ and all others except the leguminosæ, there was found to be no further development than could be accounted for by the combined nitrogen supplied. But in the case of the leguminosæ it was otherwise. Where no nitrogen had been supplied, the plants were mostly of stunted growth, having, it would seem, only

the nitrogen that the seed contained to live upon; but here and there were some that grew well, and, on examining the roots, Hellriegel and Wilfarth found that in the latter case nodules were present in quantity upon the roots, while there were none on the roots of the plants of stunted growth.

This observation set them to experiment further, and the next step was, by soaking up some fertile soil with distilled water and letting it settle, to make a water extract of it, and to add it to the pots containing the leguminous crops, but to which no nitrogen had been supplied. The plants in nearly all cases grew luxuriantly and formed nodules freely on their roots, but when the soil extract was sterilised before adding it, then there was no growth and no formation of root nodules. Peas, beans, vetches, clovers, &c., were found to act in this way, but certain others, such as lupins, serradella, &c., would not grow even with this soil extract. On watering them, however, with a similar extract, but made from a soil on which the particular crop was known to grow well, these plants, too, were found to flourish and to develop nodules, though failing to do so when the soil extract was previously sterilised.*

This observation of Hellriegel's has its counterpart in practice, inasmuch as it is known that lupins, for example, cannot be got to grow upon every soil, but that if some of the soil be taken from land on which they have been growing, and be spread as a top-dressing upon other land, then the crop may be able to establish itself. Hellriegel's experiment was, in effect, the obtaining of an extract which should contain the particular organism that favoured the growth of the particular crop, and he found that when that organism was present, the plant grew, produced nodules in abundance, and thrived proportionately, but that when the organism was excluded, by sterilisation or otherwise, there was no development of nodules and no growth. Neither Hellriegel nor his colleague Wilfarth was, however, a botanist, and it was left to Beyerinck, of Delft, Holland, to ascertain in 1888 what the precise nature of the nodules was, the result being that they were found to be bacterioid, and to contain specific organisms as bacteria.

Simultaneously with the growth and the formation of nodules came the accumulation of nitrogen in the plant, and this, being far in excess of any nitrogen supplied in seed or in extract, could, it was concluded, proceed only from the free nitrogen of the atmosphere held in the pores of the soil and fixed in the plant by means of the bacterioid nodules spoken of.

Hellriegel having thus established the connection between the development of nodules on the roots of leguminous plants and the fixation of atmospheric nitrogen, and having, moreover, shown that certain crops, such as lupins, required the presence of organisms peculiar to the soils on which these crops flourished, the way was open for the next development, that of Nobbe, the distinguished professor at Tharandt, Saxony, which is the one with which we are specially concerned now. Nobbe reasoned that if the successful growth of leguminous plants depended upon the development of the root nodules, and if certain of them could only be successfully inoculated by organisms which seemed peculiar to these individual crops, it would be well so to arrange that when a crop was grown one should make sure that the proper organisms were present. Each plant, he believed, possessed its particular kind of nodule, or, rather, these nodules contained within them bacteria which favoured, for that particular plant, the assimilation of free nitrogen. Hence he thought that by taking the nodules of healthy plants of each kind, and cultivating the organisms contained within them, he would prepare inoculating material which could be applied to like crops to that from which he had taken the nodules.

The plan of inoculating crops on the large scale by spreading over the surface of the area sown a top-dressing of soil from land where the particular crop had already been grown, was well known, though not the reasons for its success. Already for several years this had been done on a

large scale in Germany by Dr. Salfeld in his endeavour to reclaim vast tracts of moorland in the neighbourhood of Bremen, and it had been shown in Dr. Salfeld's practical field experiments that the best results attended the endeavour. But it was also known that this process of soil transference, besides being very costly, had certain disadvantages associated with it, notably, that not only would the desired organisms be transported, but that others also which were not wanted were introduced, while fungoid diseases, parasites, and other unfavourable elements might also be brought in at the same time. These difficulties Nobbe sought to avoid by adopting the method of "pure cultivation." This method consisted in taking the particular nodules, cleaning them thoroughly, breaking them open, and spreading their contents on a plate of specially prepared gelatin, on which they were then cultivated. After cultivation, one of the colonies was transferred to a second plate, and cultivation again proceeded with. This process was successively repeated, until at length what was believed to be a "pure cultivation" of the organism peculiar to the plant in question was obtained. This was, with the proper precautions, transferred to agar-gelatin contained in the bottom of a glass bottle or flask holding some 8 to 10 oz., and on this the pure cultivation was subsequently allowed to grow; the bottle was sealed, and the contents kept from the light. This is the form in which we have it before us to-day. To the material the name "Nitragin" was given, presumably from the Greek *αγειν*, Latin *agere*, "to make active." The name itself is rather an unfortunate one—at least in this country,—where its close resemblance in sound and writing to our word "nitrogen" may easily lead to its being mistaken for that. In Germany, however, where the word for nitrogen is "Stickstoff," no such confusion would be made.

Having thus secured what he believed to be the active nitrogen-fixing principle for the particular leguminous crops, Nobbe, together with his colleague Hiltner, proceeded to experiment extensively with it, and, having assured himself of its success, the next step was to introduce the material into agricultural practice and on a commercial scale. It was to a German firm—the well-known Farbwerke of Meister, Lucius, and Brüning, Höchst-on-the-Main, near Frankfurt—that the manufacture was entrusted. Dr. Pauli and Dr. Laubenheimer, the chief chemist, themselves conducted me over the works when I visited them in April last, and they kindly gave me every facility for seeing how "Nitragin" was prepared. There is, as I said, a separate department for this work, and in immediate charge of it was then Dr. Gesell, who had previously been working at Tharandt under Nobbe. Dr. Gesell was good enough to show me the methods by which, from the individual nodules of each kind of plant, the pure cultivations are prepared, and how, after they are obtained, they are bottled for use and distribution. He also showed me microscopical preparations of the different cultivations, and how the colonies are selected out for further cultivation.

It has accordingly come about that from the purely scientific work of Hellriegel, followed up by that of Nobbe, a new branch of chemical industry has been established which has for its object the rendering easier, by perfectly natural means, the fertilising of the ground for the growth of agricultural crops.

At Höchst there are separate preparations of "Nitragin" for each kind of leguminous crop, these being derived originally from the nodules of the particular plant. At the time of my visit there had been, so far, 17 different kinds of "Nitragin" prepared. But, inasmuch as Nobbe's experiments had further shown that bacteria from the nodules of certain plants did quite well also for inoculating plants belonging to families nearly related to the one taken, though they were not efficacious for those of families widely differing, the "Nitragin" preparations are classified into groups, and in the commercial practice each group is distinguished by a particular coloured label. Thus there are preparations of "Nitragin" for the common pea and for the field pea, of the pea family; for vetches and horse-bean, of the vetch family; for white, yellow, and blue lupins, of the lupin family; for red, white, and crimson clover, alsike, trefoil, cow-grass, and lucerne, of the clover family; for sainfoin, serradella, and lathyrus, while it was the intention

* This summary of Hellriegel's experiments is taken substantially from Lawes and Gilbert's paper, "The Sources of the Nitrogen of our Leguminous Crops" (Journal of the Royal Agricultural Society of England, 3rd series, vol. ii., part iv., December 1891).

shortly to add others.* The cost of a single bottle of any of the preparations is, in Germany, 2 M. 50 pf., equivalent to about half a crown here; and the contents of one bottle are supposed to be enough for inoculating half an acre of the crop which is to be grown. Accordingly, in addition to labour, the extra cost of the application would come to about 5s. an acre—a by no means large sum,—which one would be wise in incurring, if one could ensure that the crop to be grown would be able thereby to draw upon the plentiful store of atmospheric nitrogen waiting to be used free of cost.

The method of application of "Nitragin" is twofold. The simplest, and the one involving practically no cost beyond that of the purchase itself, is the method of inoculating the seed to be sown. The seed is put in a bucket, and water in sufficiency to just moisten it is poured over; the contents of the "Nitragin" bottle are made liquid by the air of very gentle warmth (not above 30° C.), and are then poured out into the water in the bucket, the bottle rinsed out with more water, and then the seed, water, and "Nitragin" are thoroughly mixed till every seed is moistened. After this the seed is dried up by adding a little of the soil from the field on which it is to be sown, or with dry sand, and is then ready for sowing in the usual way.

The other method, involving more labour, but believed to be the more effectual, is to inoculate, not the seed directly, but the soil of the field that is to be sown with the crop. This is done by taking for each half-acre of land that is to be cropped about $\frac{1}{2}$ cwt. of the earth from it, and, as before, pouring out the contents of the "Nitragin" bottle over it, and mixing the whole. It may be left exposed for a short time to dry, or more dry earth or sand may be added. Thus the soil becomes inoculated, and it is next spread evenly over the whole area to be cultivated, and should then be lightly raked or harrowed in to a depth of about 3 in., after which the seed may be sown in it as usual.

As between the two methods of inoculation—seed or soil—certainly has not yet been established as to which is the better, but Nobbe recommends that of soil inoculation, inasmuch as, though more troublesome and expensive, it would seem likely to be better, because the nodules, being developed on the root fibres, these would have a better chance to come in contact with the organisms thus distributed throughout the soil than they would if the organisms remained to some extent merely on the exterior casing of the seed. This is, however, a point to be tested by experience, though farmers would undoubtedly prefer the less cumbersome method of steeping the seed—one with which they are familiar, as in the so-called "pickling" of seed with sulphate of copper, &c., as a protection against rust and other pests.

Now there are certain very important precautions which have to be observed in regard to these "Nitragin" preparations, the neglect of which must result in failure, and which may, as they have already done, induce many to consider that "Nitragin" is of no use whatever. Trials made by practical farmers already have been known to fail through inattention to necessary details, and the Hochst-Fabrik has therefore recently issued a circular calling special notice to the precautions for use. The chief of these are: (1st) not to subject the "Nitragin" at any period to a higher temperature than that of the body, and (2nd) not to let the preparation be exposed to a strong light. In liquefying the contents only lukewarm water should be used to steep the bottle in, or merely taking it into a warm room for a short time is ample. The most practical way, as Dr. Pauli laughingly showed me, is to put the bottle for a few minutes in one's trouser pocket! The bottle, too, should be kept with a wrapper over it.

Another precaution that must be observed is not to allow either the inoculated seed or the earth that has been similarly inoculated to lie about for any length of time, nor exposed to any strong light, before applying it to the land. The operation of infecting seed or soil must be done just preparatory to application to the land, or failure will result. This should be carried out in a cool, shaded place, or the activity of the bacteria will be imperilled.

Another necessary caution in trying experiments with "Nitragin" is that, inasmuch as "Nitragin" only provides a nitrogenous manuring, the failure of it, where such is noticed, may be possibly due to the absence of a sufficient supply of mineral food in the form of phosphates, potash, &c. It is therefore advisable in such experiments to apply phosphatic and potassic manures as well, in order to make sure of their presence in sufficiency. Another mistake which I find farmers frequently make is to think that the application of "Nitragin" to an already established crop of clover, &c. will do good. It is at the early stages of the growth that the rootlets get the nodules formed upon them, and that their activity is greatest, whereas as the plant gets to maturity the nodules, as Lawes and Gilbert have shown, get used up, having parted with their nitrogen, and disappear.

As regards the duration of the activity of "Nitragin," it is believed that the bacteria will retain their efficacy for a period of about four months, and probably still longer, but, to be on the safe side, the preparation should certainly not be above two months old.

This is a fitting point at which to review the conclusions arrived at by Nobbe from his examination of the different "pure cultivations" and of their action in the case of individual leguminous crops.

Nobbe was led to conclude that each organism probably had its individual efficacy for the particular crop from which it was derived, and either none or a weakened one for other leguminous plants than that one. This he found by experiment to be in a more or less degree the case. When he took pure cultivations from the nodules of the pea plant he found that inoculating the pea plant with it produced excellent results, while if he tried it with vetches, the result, though good, was not so good as before; on the other hand, the inoculation with the pea cultivation did not produce any effect on clover, serradella, &c., and if he took pure cultivations from clover they would not do any good with peas, though very efficacious for plants of the clover family.

Thus the difference was one rather of degree, the activity being greatest for the plant from which the organism was derived, and diminishing gradually as one went to plants less nearly related to the original one. Further than this, Nobbe was led to conclude that the organisms under the influence of symbiosis with the particular plant underwent some change by which their descendants became so impressed by the plant as to be capable afterwards of only influencing to the full extent those plants which belonged to the same family as the parent one, but lost the power more or less for those not closely related to it. Hence, in the case of a soil heavily cropped for some time with a leguminous crop, the organisms might be so impressed with the character of the particular crop that, when another not nearly allied to it was put in, the bacteria were not able to influence it, and, in such a case, inoculation with bacteria of the kind derived from nodules of the new crop—in short, with the proper kind of "Nitragin"—might be required in order to produce the formation of nodules, the assimilation of nitrogen, and the healthy growth of the new plant.

Thus a state of things might quite well occur, as was shown to be the case with lupins, when, though leguminous crops had been grown and the soil had abundance of organisms in it, yet these were not of the right kind, through being too strongly impressed with the characteristics derived from the parent plant.

Nobbe also made experiments in order to determine in what condition of the soil the nodule-activity was most efficient, and he found that it was when the soil-nitrogen was nearly used up that the nodules showed the most activity, and that the difference between an inoculated crop and one not inoculated was the most marked. If there was abundance of soil-nitrogen, then it was quite likely that no difference would be found between plots inoculated and those not inoculated. It followed also from this that plants, such as peas, vetches, &c., which grew quickly and were likely to use up the soil-nitrogen in their rapid growth, would be better ones for showing the influence of inoculation than other more slowly-growing crops like clover.

I certainly came away from Germany with the impression that it was impossible, from microscopical examination of

* Since the above was written I hear that the following have been added:—*Vicia villosa*, Bokhara clover, and kidney vetch.

the bacteria, to say definitely whether they had come from nodules of the pea, or lucerne, or clover, and so on. But I have since been told that this is not altogether the case; for, though without previous knowledge of their origin, one might not be justified in pronouncing distinctly that this is a red clover bacterium or the other a lucerne bacterium, yet there are certain distinctions in appearance which may serve to the identification of each, more or less closely. This has been communicated to me recently by Mr. F. R. Armytage, of Shrewsbury, who has been working at the subject for the last two or three years, and he has also sent me some photographs taken from cultivations of several different kinds. These he has allowed me to use, and certainly it would appear from them that there is not such a want of definition as I was led to suppose. The photographs, and especially that of gorse, do show distinctive features by which it would seem that they might quite well be differentiated. But on this point I have no personal knowledge, and merely append the photographs; they are taken at about 720 diameters, through the microscope. Mr. Armytage writes:—

"I especially invite your attention to the one of 'Gorse.' I have not found this form (No. 14 on the diagram) in the nodules from any other plant, the nearest approach being the zomna-shaped No. 13 from Broom. No. 15 represents what I invariably find on lucerne, and Bokhara clover (a near relation) affords organisms somewhat similar. No. 11 is very characteristic of a large number of slides of *Vicia sativa*—note the repeated branching. A form resembling No. 5, I always find on *Trifolium*."

FORMS OF ORGANISMS FOUND IN THE NODULES ON ROOTS OF LEGUMINOUS PLANTS.

[Copyright.] ORGANISMS FROM GORSE.

I have subsequently received independently from Mr. John Golding, of University College, Nottingham, some similar photographs, illustrating the differentiations which Mr. Armytage points out. Mr. Golding adds: "It is found that on cultivating these organisms on gelatin or other nutritive media the differences disappear, and the organisms cannot be distinguished from one another by the aid of the microscope." This is significant in view of what I heard from Dr. Nobbe.

We come next to consider what the results of experiment with "Nitragin" on a practical scale on ordinary agricultural soils, and not merely by pot culture in special soil,

have been. The obtaining of "Nitragin" in a commercial way not having been accomplished until the time of my visit to Höchst (April 1896), the season was already rather far advanced to enable many, even in Germany, to experiment with it. Still I did see two places where "Nitragin" had been applied to acre plots of crops of peas and tares on ordinary land, side by side being plots similarly sown, but not treated with "Nitragin." The most that I could say was that the treated plots looked just as well, perhaps a little better at this early stage, than the untreated ones, and on examining the roots there certainly appeared to be more nodules where "Nitragin" had been used. Through the kindness of the directors of the Höchst Farbwerke I was supplied with several bottles of the special "Nitragin" for the leguminous crops we generally cultivate in this country, and with these I arranged for the carrying out, so far as it was still possible, of some practical field trials with the new material, under ordinary conditions of farming. Of these I must give a short description, and exhibit also a few photographs, which show some of the crops at two different stages of their growth. But in mentioning these experiments I must do so with great reserve, for not only was the season too advanced for trying them satisfactorily, and so the results could at best be but tentative in character, for, as you all know, the summer was one of an exceptionally hot and dry character, most unfavourable in every way for the growth of clover and other leguminous crops, and for the carrying to any satisfactory issue of an experiment of this kind. So I can only give them for what they are worth, and with all reserve, but I have at least set them out just as they were given me, or found by me to be, whether good or bad, in favour of or against the theory put forward. One trial was carried on on a farm in Sussex, with vetches; on one half-acre of land the seed was first inoculated, and on the other half-acre not. In both cases the crop was an excellent one, there being no apparent

 II.—Seed treated with "Nitragin."
 III.—Not treated.

difference between them. The vetches were to be ploughed in as green-manuring for a crop of wheat, and so no weighing results are yet obtainable. I found, however, that the soil was one of a rich nature, and as the vetches grew exceedingly well when not inoculated, there was practically no scope for the "Nitragin" telling further, and, no doubt, there were already present in the soil the necessary organisms, as shown by the growth of the crop on the untreated plot. So this was not conclusive. At the Woburn experimental farm I was able, with considerable difficulty, in consequence of the prolonged drought, to commence a series of experiments myself; and, in addition, two other series were undertaken, with my supervision, by Mr. Howard Ryland, of Moxhull Park, Erdington, Warwickshire, and by Messrs. Sutton and Sons, at Reading. In every case, however, the drought so interfered with the sowing and coming up of the crops that, apart from its being a first year's trial, the experiments can only be regarded as of a preliminary nature.

Fig. 6.

FRENCH BEANS (June 9, 1896).

- IX.—Soil treated with "Nitragin."
 X.—Seed treated with "Nitragin."
 XI.—Not treated.

At the Woburn experimental farm I made experiments with the following crops:—Beans, peas, tares, lucerne, sainfoin, serradella, red clover, white clover, alsike, cow-grass, and trefoil. Of these, the beans, peas, and tares would be the only crops to finish in the one season, and as I only had the "Nitragin" early in May, the proper time for sowing the crops was virtually past. Moreover, there were only still available odd bits of ground, and not situated as I would like to have them for exact experiment. The land was ordinary agricultural land—a light sandy loam—and all three crops had been grown, at one time or another, in previous years, so that there was no difficulty, that we knew of, respecting their growth. I tried one half of each plot with soil inoculated with the "Nitragin" for the particular crop, and the other half untreated. Owing to the late sowing and the great drought, the plants did not come to

maturity at the proper time, and had to be cut green. All that I could really say about them was, that the inoculated plots were as good, but not better, than the untreated ones. When the plants began to grow, I had individual ones taken up, in order to examine the rootlets. In the case of the beans and peas, it certainly did seem to be the case that root development was greater on the "Nitragin"-treated plots than on the untreated, but nodules were plentiful on each. With vetches, the untreated plants seemed the better. On similar odd plots on the same field, lucerne, sainfoin, and serradella were tried, each in three ways:

Fig. 7.

BROAD BEANS (July 14, 1896).

IV.—Soil treated with "Nitragin."

V.—Seed treated with "Nitragin."

VI.—Not treated.

(a) soil treated with "Nitragin"; (b) seed treated with "Nitragin"; (c) untreated. Here, again, the drought seriously interfered, and from the newly-sown lots only small first cuttings could be obtained. In the case of both lucerne and sainfoin, rather the best plots were those where the soil had been inoculated previous to sowing, but to give the actual weights obtained would be misleading. These plots will continue for another year or more.

The more extensive series were the experiments on different clovers (red, white, alsike, cow-grass) and trefoil, but from these, more especially in such a dry season, no cutting would be obtained the first year, and the plots must stand another season before anything can be concluded from them. The plots here were on land that was known, by previous experience, to be "clover-sick," it having been found impossible to keep any of the clovers growing on it for above two years. The principle on which the plots were arranged was that there were seven small plots in each of the five crops (*viz.*, four clovers—red, white, alsike, cow-grass—and trefoil). One plot was left untreated, one sown with mineral manures (superphosphate, sulphate of potash, and gypsum) and nitrate of soda, but not inoculated. On a third plot the seed was inoculated with the appropriate "Nitragin." On a fourth the soil was similarly infected, while the other three plots were given soil inoculated with "Nitragin" of kinds other than that specially designed for it. Red clover, for example, had white clover,

trefoil, and lucerne "Nitragin" respectively; trefoil had red clover, white clover, and lucerne "Nitragin," and so on. This plan was, of course, devised not only for telling whether inoculation was beneficial, but whether soil or seed inoculation was preferable, and whether inoculation with "Nitragin" from plants other than the particular one grown would be effectual or not, as well as whether an equal result could not be obtained by using nitrate of soda along with mineral manures, and without inoculation.

Mr. Howard Ryland, of Moxhull Park, Erdington, Warwickshire—a member of the Council of the Royal Agricultural Society—carried out this year also some similar experiments on a garden soil. The crops tried were green peas, broad beans, sweet peas, and French beans; while, in a further trial, green peas were grown in builders' sand. The inoculating "Nitragin" was here, in all cases, that of "*Pisum sativum*," the pea. Sowing could not be done before May 16th, and the drought interfered most seriously with the results. Soil inoculation and seed inoculation were tried, as against no treatment. Plants were taken up from the different plots on two occasions, *viz.*, on June 9th and on July 16th, and these were photographed. The photographs, which I set out here, will show how far any deductions may be drawn. Taking them as a whole, it may be generally said that inoculation of the soil proved the most efficacious, and that both it and inoculation of the seed were superior to no treatment, although there were one or two cases where the untreated plants were the better, and two cases where there was nothing to choose. Green peas, broad beans, and sweet peas were benefited; in the case of French beans, the result was doubtful. Enlarged photographs of the roots of the plants were also taken, and here, too, the treated broad beans, sweet peas, and green peas show the better developed roots and more nodules. The greatest difference was in the sweet peas, the growth of top, and also the root development, being much greater where the soil was inoculated than where it was not.

The last set of English experiments that I have to mention is one kindly undertaken by Messrs. Sutton and Sons, of Reading, on their ordinary trial ground. This is a long series, and includes the following 15 crops:—Sainfoin, lucerne, red clover, white clover, kidney vetch, vetch, serradella, *lathyrus silvestris*, yellow lupin, blue lupin, melilotus, trefoil, trifolium, peas, and beans. Here again the inoculation of the soil and that of the seed have been compared, and "Nitragin" has been used for other crops than those for which it was primarily intended. In all, there are 45 different plots, and what gives additional interest to the trial is, that on the plots sown with single-year crops—like peas, beans, tares, &c.—a corn crop (wheat) will be grown after them, in order to see if the result of the inoculation has been an increase in the amount of nitrogen accumulated in the soil. As at the other experimental spots, the dry season militated most severely against success, and the trial must be considered here, too, as mainly of a tentative character. Sowing was done from May 14th to May 22nd, and notes of the appearances of the different plots have been regularly taken by Messrs. Sutton, while I inspected the experiments myself on July 3rd. At this time I examined, in company with Mr. Leonard Sutton, individual plants from each plot, chiefly with a view to seeing if there was more root growth and more nodule formation on the inoculated plots than on those not so treated. The general conclusion arrived at on that date was that, taking the crops generally, there was no marked increase visible so far as top growth went, except in one or two cases, though the treated plots were, on the whole, the better; but that, as regards root growth, this was decidedly stronger on the inoculated plots, and nodule formation was more active. Thus, out of the 15 different crops, in the case of 12 of them there was more root growth on the treated than on the untreated plots, while in three instances only was the reverse the experience. The three exceptions were kidney vetch, peas, and beans, the last two inoculated with "Nitragin" from lucerne and also from vicia faba. It should be stated, however, that beans had previously grown on the land, and hence it was most probable that the organisms suitable for bean and pea growth were already abundantly present. Of the crops that were sufficiently advanced to give a crop or cutting the first year,

the following are the comparative results obtained in October on the small experimental plots:—

Crop.	Not Treated.	Treated with appropriate "Nitragin."	Treated with "Nitragin" of another Crop.
	Green Weight, Lb.	Green Weight, Lb.	Green Weight, "Nitragin," Lb.
1. Lucerne.....	30½	35½	(Sainfoin) 29½
2. Red clover.....	50½	57	(White clover) 59
			(Lucerne) 101½
3. Yellow lupins.....	51	..	(Red clover) 86
			(White clover) 74
4. Bokhara clover....	80	..	(Lucerne) 82
5. Crimson clover.....	28	..	(Red clover) 31
6. Serradella.....	175½	..	(Lucerne) 145
			(Red clover) 165
7. Trefoil.....	91½	..	(White clover) 78½
8. Broad beans.....	Seed. 3½	Seed. 3	(Sainfoin) 4

I have given the foregoing results just as they have been obtained, without any selection whatever of what seemed to tell in favour of the theory advanced. Another point is noticeable, that, my object being primarily to see whether the method of soil and seed inoculation was likely to be of any value in practical agriculture in this country, I did not select soils which were the most likely to respond favourably, but such as would be in ordinary cultivation. Though I am free to allow that, chiefly owing to an adverse season, the experiments at none of the three stations can be considered as fully satisfactory or as in any way conclusive, yet as a first year's trial, under conditions most unfavourable, I think you will agree with me that there are sufficient indications that the practice will be one attended with benefit. How far that benefit will extend must depend largely upon the nature of the soil and what has been previously cultivated on it. The general conclusion may, I think, so far, be fairly drawn that inoculation of leguminous crops, while not giving lesser but frequently increased growth, does certainly, as a rule, produce greater root development and more nodule formation. As between seed and soil inoculation there is not conclusive evidence, but the balance seems to be in favour of soil inoculation. Nor does the necessity for inoculation with the "Nitragin" derived from the same crop as that to which it is applied come out at all forcibly. Granted that there is more root development, the interesting point to determine is whether the after-crop will be better—whether, in fact, the storing up of nitrogen can be utilised. This will be the work of another year, as also the elucidation of the main question by a wider series of practical trials.

DISCUSSION.

The CHAIRMAN having invited discussion,

Dr. H. E. ARMSTRONG said that as he had visited the works where "Nitragin" was produced, in September last, he might say a few words about it, merely in order to start discussion. He agreed with Dr. Voelcker that the manufacture of such a product was a striking exemplification of German chemical enterprise at the present day. He did not know a chemical works anywhere which, in so small a compass, showed such an extraordinary amount of originality and enterprise as did that of Messrs. Meister, Lucius, and Brünig. "Nitragin" was only one of their new products: it was well known that they had recently taken up the manufacture of diphtheria serum on a large scale, and they were manufacturers of antipyrine, as well as of aniline colours. He might refer also to the use they made of formic aldehyde, the manufacture of which had risen from the infinitesimal quantity produced in 1867, when it was discovered by Hofmann, to many tons at the present day. These were illustrations of what was done at Höchst with the aid, not of forty chemists, as stated by Dr. Voelcker, but of over a hundred; and there was no doubt that the

results obtained amply justified the policy of the company in question. Turning to the paper under notice, he would remark that all the observations made by Hellriegel had been confirmed by Lawes and Gilbert at Rothamsted. Rothamsted had throughout taken an important part in this work, which had been one of the greatest surprises brought to the notice of chemists in recent years. Nitrogen was generally regarded as an element of extraordinary inactivity; but there could be no question that atmospheric nitrogen was absorbed by the nodules which had been described, although no one at present had the faintest idea how. No case was yet known to chemists of gaseous nitrogen being absorbed or entering into association with any other element at low temperatures. The action therefore must be one of a very unusual and striking character, and difficult to understand. No doubt great discoveries would await the further investigation of the subject in that direction, for if we could succeed in combining atmospheric nitrogen with hydrogen or oxygen, and so make artificial ammonia or nitrate, it would be a most important achievement for agriculture. From that point of view the further investigation of the low-temperature chemistry of nitrogen was of the deepest interest to the Society. Probably, however, the nodules performed some other function besides that of merely leading to the absorption of nitrogen, for apparently leguminous plants could not grow without them. Directly the soil was infected with the nodules—provided the necessary mineral constituents were present—a vigorous growth set in, which was accompanied by absorption of nitrogen. Under normal conditions the plant, apparently, to a large extent, availed themselves of the soil nitrogen, and only when that failed them did they assimilate atmospheric nitrogen. So the function of the nodule was a complex one. The great question with regard to the use of the different "Nitragins" as fertilisers to be answered in the future was, how soon would exhaustion, or one or other of the varieties of leguminous sicknesses, set in? What had been done so far did not at all explain the cause of clover sickness. Sir J. B. Lawes had been growing clover in his own garden for forty-five years, yet in his fields he could not sow two crops in succession. That was good evidence that the failure of the plant to prosper was not due to the exhaustion of the organisms. The only difference between the two plots was that the one in the garden had been manured as a kitchen garden for many generations, and there was a huge accumulation of the proper food in the soil, whereas apparently in the neighbouring field, as there was no such store of available nutriment, the supply was soon used up, and it took a long time before the conditions were such as to enable another crop of the same sort to be raised.

Dr. G. SCHACK-SOMMER said that there could be no doubt of the importance of the discoveries brought forward by the author. At the same time he was unable to see how, from a practical point of view, they could be made useful in agriculture. If the discovery had been made in the 'Seventies, when sulphate of ammonia was 24l. per ton, it might have been of great value, but with sulphate at 6l. 17s. 6d. it was quite another thing. Nothing that Dr. Voelcker had said indicated any advantage in bringing the nitrogen into the plants by means of these bacteria, in distinction to taking it from the soil to which it had been brought in the form of manure. It was therefore only a question of pounds, shillings, and pence. True, the author had referred to the soil itself being enriched by the organisms; but that was only in case they allowed the plant itself to decompose there—a practice which was followed on the Continent long before agricultural chemistry had reached its present condition. If, however, plants were removed as a crop, they would take with them all the nitrogen they had gathered from the air. He could therefore only regard the discovery brought before them in the light of a very interesting experiment.

Dr. W. SOMERVILLE had made experiments with "Nitragin" at about the same time as the author, namely in May last. He had tried it on various crops, *viz.*, red clover, white clover, lucerne, peas, and beans, and had used the utmost care in following the treatment recommended by Meister,

Lucius, and Brüning. He had used it in the two ways described by the author, namely, by adding it directly to the soil, and by mixing the liquefied "Nitragin" with water and then applying the liquid to the crop by means of an ordinary garden can. He had tried it on peas in his own garden, in which such plants had grown for years; on clover in pots and in the open; on lucerne in pots and in the garden; and on a field of lucerne sown two years before. This lucerne, sown in 1895, was looking sickly in the spring of 1896, and was apparently pining for something, possibly the required organism. He regretted to say, however, that in every experiment, with the single exception of the peas, he had failed to get any good results from the use of the "Nitragin." He further regretted to note that the firm interested in the production of the material had already found it necessary to more or less discount failures by issuing a letter to the German press in which they explained that the failures which were so frequently referred to by correspondents were due either to exposing the material to too much light or too much heat, or keeping it too long. From this, and from his own experience, he concluded that "Nitragin," however interesting from a scientific point of view, was not likely to prove the salvation of English agriculture.

Dr. H. E. ARMSTRONG wished it to be clearly understood that Dr. Somerville had applied the "Nitragin" by watering growing plants, and he thought it unjust that he should sweepingly condemn the invention when he had used it in such a way as to give him no right to expect good results from it.

Dr. SOMERVILLE replied that his experiments were not confined to watering growing plants. He had also applied the "Nitragin" by mixing it with the seed and with the soil, and in no case did beneficial results follow.

Dr. VOELCKER wished it to be clearly stated whether Dr. Somerville had applied the "Nitragin" to growing crops, or whether it was used when the seed was sown.

Dr. SOMERVILLE replied that he had used it both on crops actually growing and on crops sown in the spring, and also, in the case of lucerne, on the crops sown in the spring of 1895, as well as in the spring of 1896.

Dr. VOELCKER was still not clear on one point. Dr. Somerville had said he had applied "Nitragin" to crops sown in the spring of 1896. Were the crops sown previous to the application of the "Nitragin," and, if so, how long previous?

Dr. SOMERVILLE replied that they had in some cases taken the seed and actually mixed it with the solution of "Nitragin," adding just sufficient soil to bring the seed into condition for sowing as recommended. They had also applied "Nitragin" to other plots by means of an ordinary garden watering-can.

Dr. S. RIDEAL could not claim to have any special knowledge of the subject before the meeting, but would like to mention that he had recently met Dr. Clark, the lecturer on Rural Economics at Leeds University, who was then conducting experiments with "Nitragin," from which he had obtained very favourable results. It might be desirable to ask Dr. Clark to state these results in the form of an addendum to the paper. He would suggest also that the failure to obtain equally good results in all cases might be due to the fact that the organisms concerned degenerated, owing to artificial reproduction. He would like to ask the author if any experiments had been undertaken to ascertain whether any such degeneration during the cultivation of the organisms on gelatin took place. It was possible, too, that these organisms, as they seemed to be capable of living on gelatin without atmospheric nitrogen, might prove useful, not only in agriculture, but as a means of breaking down nitrogenous substances in sewage filter-beds. With regard to the variation of the organisms in form, it struck him that that might be accounted for by a difference in the age of the organisms, it being well known that that was the case with respect to other bacteria. Referring to Dr. Armstrong's remarks that certain English hospitals had obtained diph-

theria serum from the manufacturers of "Nitragin," it was satisfactory to know that that body was now being manufactured in this country, and that the serum produced here was much more powerful than that supplied from Germany.

Dr. BERNARD DYER considered that the most important aspect of "Nitragin" was its possible bearing upon clover sickness. The nature of that sickness was still involved in mystery, but there was a growing feeling that there was probably some connection between it and the organisms treated of in Dr. Voelcker's paper, and that probably the solution of the question might be found in connection with their further study. One difficulty, however, in the way of accepting this view was this: If red clover, for instance, had its special organism, and if that particular organism had no other function in the soil but to ensure the nutrition of red clover, one would imagine that, in the ordinary rotation of crops, the organisms would be more likely to exist in sufficient number and vigour every four years rather than in every eight years. Such, however, was not the case. Possibly the organisms themselves might be subject to diseases or parasites, causing them to die out or become weaker in their action, and the reinforcement of the soil from a new stock might thus become necessary. Such was undoubtedly the case in other and higher forms of vegetable life. In the light of the facts brought before them by the author it was easy to understand how lupins were difficult of growth in this country, while on the Continent they could be grown almost anywhere. Reference had been made to the classical researches of Dr. Voelcker's father in 1868 on the benefits of a clover crop as a preparatory crop for wheat. He would like also to refer to another paper by the same author of considerably earlier date, *viz.*, in 1850, on the subject of lupins, showing how he had made an effort to get lupins acclimatised and taken up in this country, and had given a most interesting account of his experiments. On one farm he grew them without difficulty, while on another they could not be induced to grow, no doubt because the special microbes were absent. There was one point upon which he would be glad to be further informed. In making his comparative experiments with ordinary seed and seed treated with "Nitragin" by soaking, did Dr. Voelcker also soak the untreated seed? It was a well-known fact that the mere soaking of seed, apart from any other treatment, often had a most important effect on the germination of that seed, and this might affect in some cases the subsequent vigour of the plant.

Mr. T. ROYLE remarked that it was a common practice in South Carolina to prepare land for the cultivation of wheat or other grain by sowing it with cow peas, and ploughing the crop in to act as a fertiliser.

Mr. P. DVOROVITCH wished to draw attention to one point which had not been referred to in the paper. It was, he considered, highly important for the success of experiments with such fertilisers as "Nitragin," to analyse the soil in every case, in order to determine whether the various constituents required for success were present and bore the proper relation one to another. It was most important, for instance, that the soil should contain the necessary mineral constituents. If these bore the proper relation to the "Nitragin," the results would, he thought, be better.

Mr. LEONARD SUTTON agreed with the author that in arriving at an opinion as to the advantages of using this fertiliser, it was desirable to weigh the crops produced. He did not gather from Dr. Somerville's remarks that he had subjected his results to that test, and thought that probably, had he done so, he might have found a decided difference in them over those produced by untreated soil or seed, though the difference might not be very apparent to the eye.

Dr. SOMERVILLE replied that all the crops to which he referred were carefully weighed and tested, and although he had not the weights with him, the meeting might take his word that everything he had said was warranted by the actual results obtained.

Dr. J. A. VOELCKER, in reply, thanked the meeting for the kind attention which they had given to his paper. He

did not expect to find their opinion unanimous, and his only object was to put facts impartially before them, so that each might judge for himself. It certainly seemed to him that the discovery had great possibilities before it. The practical application of the work of Hellriegel and Wilfarth was this: it was established that certain leguminous plants thrive well when they got on their roots a certain nodular development, and it was further found that this development did not occur unless the roots came in contact with certain organisms. What one had to do, therefore, was to make sure that these conditions were fulfilled; and Nobbe had, he thought, conclusively shown that the application of "Nitragin" would fulfil them, thus enabling the crop to take the nitrogen from the air and use it for its own benefit. There might be something in Dr. Rideal's suggestion, that degeneration of the organisms occurred from age or from other circumstances, but he had no evidence on that point at present. The principle of the discovery seemed to him perfectly rational and scientific, and if its application was not yet the best attainable, no doubt someone would, by further study of the question, enable them to arrive at the best method, and he hoped that that result would be attained in England. He was much obliged to Dr. Armstrong for calling attention to possible further developments in regard to the absorption of nitrogen under conditions of low temperatures. He was also obliged to Dr. Dyer for his suggestions. "Clover sickness" was one of the great questions in agriculture which had not yet been solved. Some of the experiments related had been carried out on land known to be "clover-sick." Dr. Schaack-Sommer was perfectly correct in his remarks about the decline in the price of ammonium sulphate. He would point out, however, that if "Nitragin" was possessed of the virtues attributed to it, farmers could by using it get, at a cost of five shillings per acre, what they would have to pay 3*l.* for in the shape of sulphate of ammonia. Reference had been made to his father's statements as to the advantage of preparing for a wheat crop by growing a crop of clover, and now one knew the reasons for this. The farmer who adopted this new fertiliser and was able to raise by it a crop of clover where he meant afterwards to sow wheat, would thus become independent of sulphate of ammonia at 6*l.* 17*s.* 6*d.* per ton. With regard to Dr. Somerville's remarks, he would point out that, unless one made sure first of all that the land to which he applied the fertiliser was without the required organisms, he could not say whether any advantage would result from using it, but here again he claimed that Hellriegel's experiments amply proved that where the organisms were not present, a considerable advantage accrued from inoculating the soil by means of "Nitragin." The question had also been raised as to whether the difference in appearance of the various organisms which he had been able, through the kindness of Mr. Armytage, to show them, was the result of age or of variety. He regretted that he was not able to express any decided opinion on that point, but could only put before them such evidence as he had, and it was a matter to which he would certainly devote further attention. Dr. Dyer had expressed the opinion that in control experiments it was desirable to soak the seed, whether it was treated or not. The purpose of the experiments, however, was to determine whether this discovery was adaptable in practice, and in practical agriculture it had not hitherto been usual for the farmer to soak his seed. Therefore, in his opinion, the proper course to adopt was to treat the one half in the usual way, and the other half in the way directed for the use of "Nitragin." He quite agreed with Mr. Dvorkovitch as to the importance of ascertaining that the mineral constituents were present in the soil and in sufficiency, and perhaps this point had some bearing on Dr. Somerville's results.

The CHAIRMAN promised that Dr. Rideal's suggestion should be duly considered. Dr. Voelker's paper had been treated in a scientific manner, and he hoped that, undaunted by isolated failures, the experiments would be followed up, and that yet one more chemical industry might be based on the achievements of bacteriological science, to which chemists had so largely contributed. Chemists were scientific detectives, and could disregard no clue which might assist their inquiries.

Meeting held Wednesday, November 4th, 1896.

DR. C. A. KOHN IN THE CHAIR.

THE SYNTHESIS OF PHYSIOLOGICALLY ACTIVE ORGANIC COMPOUNDS.

CHARLES A. KOHN, PH.D., D.S.C.

Lecturer on Organic Chemistry, University College, Liverpool.

THE relationship of pure science to its practical application stands on a very different footing to-day from that of the past. No longer does the manufacturer base his work on changes already studied in the chemical laboratory; but from his investigations new light has been repeatedly thrown upon subjects of the greatest theoretical importance, and from him suggestions as to new lines of inquiry have often come.

The work of the pure scientist and of the technologist are inseparable, and the fact that this Society of Chemical Industry has always welcomed teachers of science amongst its members is a happy sign, for their mutual advantage.

Whilst, therefore, I express my appreciation of the honour you have done me by electing me to the chairmanship of this, the oldest section of the Society, I feel also that you have honoured this College with which I am connected.

Few sections of the Society have maintained the stability and the even prosperity of the Liverpool Section, and I gladly take this opportunity of attributing our success to the continued help and unabated interest we still enjoy from those who have preceded me in this chair, and to whom the inception of the Society itself was primarily due.

To follow such men, whose work is recorded for all time in the chemical industries of this district, is no easy task; and whilst I ask for your indulgence, let me also claim your aid to keep the status of this section and the standard of its work at least on a level with the past.

The industrial developments of organic chemistry stand out among the most marked achievements of applied science. From soap to explosives, from brewing to hutter, the science of organic chemistry has played its part with marked success. The hydrocarbon formed by the direct union of the elements is now prepared on a manufacturing scale for the enrichment of illuminating gas; the successful developments of the aniline colour industry need no accentuation; and more recently electrolysis has come to take its share in the preparation of organic compounds. The field of industrial organic chemistry is comparable in extent with that of the so-called "heavy chemicals"; and if in the choice of a subject for my address I have taken one

of the less known and less prominent branches of organic chemical industry, it is partly because I believe it is one in which important developments are likely to occur, and also because it to-day lies somewhat nearer than other branches to my natural home—the chemical laboratory.

The synthesis of physiologically active organic compounds may be regarded as dating from Liebreich's investigations on the action of chloral in 1868. The discovery that led Liebig in 1832 to the preparation of chloroform formed the basis for Liebreich's work. The importance of knowing whether a substance is decomposed or not on passing through the body, and, if decomposed, of knowing further, not only the decomposition products, but also their therapeutic effect, are the points laid down by Liebreich as fundamental for pharmacological investigations. How clearly he recognised this is evident in the choice of chloral and of tri-chloroacetic acid for his experiments. Such considerations still guide the pharmacologist; their far-reaching import has extended, not only to the preparation of new drugs, but also to the recognition of valuable therapeutic properties in substances like acetanilide, which for so many years reposed innocently on the shelves of our chemical museums. True, that side by side with success there are many failures to record; but permit me to remind you how exceptionally difficult and arduous a form of experimental inquiry devolves upon the physiologist in the investigation of the therapeutic action of drugs.

The complexity of the animal body, the many functions it exercises, the innumerable and mutually dependent processes which take place in it—these are all factors that contribute to the difficulty of investigation. These difficulties are not so much in regard to the tracing of any final effect a drug may produce, but, in attributing its action to the correct function or process by which the observed result has been attained.

To enter into any detailed considerations in regard to such inquiries is beyond my purpose and powers, but a few of the more simple causes that may complicate the physiological effect of a drug may not be out of place.

The physiologist distinguishes between the direct and the indirect action of a drug. For instance, curare kills by paralysing the ends of the motor nerves; this is its direct action. But under certain circumstances death is preceded by convulsions due to a secondary, or indirect, reaction of the drug.

Again, a drug exerts a local action on that part of the body to which it is applied. But this action may give rise to symptoms in other remote parts of the body: a secondary effect, which in many cases—as in the use of quinine as an antipyretic—is of such a nature as to prevent its application in practice.

The effect of a drug varies also with the quantity. Atropine, for instance, in small doses slows the pulse, in larger quantities it quickens the beating, and in very large quantities again slows it. Further, the quantity of a drug required to produce a certain result is no absolute value. What has to be considered is the quantity of the drug acting, and this is related to the weight of the body acted upon, to the rapidity with which the drug is absorbed in the system, and the proportion this bears to the rapidity of excretion.

The mode of administration also effects the action of a drug. Thus kairine and antipyrine injected subcutaneously have a much greater effect than when taken into the stomach by the mouth.

Such are a few among the many points the physiologist has to weigh in assigning to a drug what is called its "action," or better, its "reaction," with the body acted upon. The importance of such considerations are fully dealt with in the "Croonian Lectures" for 1889, by Prof. T. Lauder Brunton.

Within the last 14 years some 200 synthetically prepared organic compounds have been introduced for therapeutic purposes. Comparatively few of these have "come to stay," but they have all added their quota in developing a knowledge of the relation of chemical constitution to physiological action—a knowledge without which the therapeutic value of such bodies as antipyrine, antifebrine,

and phenacetine would never have been recognised. Most of these drugs may be conveniently grouped under the three headings of—

- (1.) *Narcotics.*
- (2.) *Antiseptics.*
- (3.) *Antipyretics.*

The properties of some assign them to more than one of these groups.

I do not propose to detail to you the long list of substances which this classification includes, but to attempt to show, in some of the best investigated instances, along what lines chemical synthesis has advanced in the preparation of physiologically active compounds.

Narcotics—bodies which have the power of retarding the nerve functions—include anaesthetics and hypnotics.

Among the simpler derivatives of the hydrocarbons a similarity in physiological properties is found to run side by side with an analogous constitution. The primary alcohols of the aliphatic series have all a toxic effect. Their main action consists in paralysing the nerve centres, and this effect increases in intensity with an increase in the molecular weight of the alcohol, until the solid alcohols are approached, when, owing to their insolubility, and consequent too sparing absorption by the system, they cease to have any physiological effect at all.

Narcotics act upon the most highly organised nerve centres first, whilst the most simple and at the same time most automatic and stable centres are affected last. The order in which these nerve centres are rendered inactive differs amongst the various members of the alcohol group. Some induce sleep as the first result of their action, which only passes into anaesthesia when large doses are employed. Such bodies are valuable as hypnotics; their action is weak but prolonged. Others act rapidly and more energetically, so that, provided they are quickly eliminated, and cease to act very shortly after being administered, they fulfil the conditions required by a good anaesthetic. Consequently bodies of low molecular weight and high volatility are included in the latter group, whilst the former contains substances having a relatively high molecular weight, and which are only slowly absorbed by the blood. This is illustrated in the value of tertiary amyl alcohol (amylen hydrate) $(\text{CH}_3)_2\text{C}(\text{OH})\cdot\text{C}_2\text{H}_5$, as a hypnotic; it boils at 102.5°C . It passes through the system just as ethyl alcohol does, being converted into carbon dioxide and water. Its more prolonged action is to be directly traced to this decreased volatility and solubility.

The halogen substitution products of the lower aliphatic hydrocarbons are characteristic anaesthetics, the well-known properties of chloroform being shared by methyl- and methylene-chloride. The volatility of the former has restricted its use to that of a local anaesthetic, and methylene-chloride, CH_2Cl_2 (first recommended by Richardson as an anaesthetic) has not found much favour. Ethylene di-bromide, $\text{C}_2\text{H}_4\text{Br}_2$, B.P. 131°C ., whilst retaining the hypnotic effect of bromine, appears to have very little anaesthetic action. This again illustrates the influence of a high molecular weight and boiling point. Donath has recommended its use as an anti-epileptic from the standpoint that the chronic poisoning effects, that are produced when potassium bromide is employed, are due to the metal, and that this would be obviated by introducing the bromine in combination with an hydrocarbon residue, which would be readily and completely oxidised in its passage through the body. Its value for this purpose requires confirmation.

The oxidation products of the alcohols, the aldehydes, preserve the hypnotic power of the former, but they exercise an objectionable irritant action on the mucous membrane, especially in the case of the lower members. The lowest member of the group presents, consistently with its chemical behaviour, some marked differences to its higher homologues. Both formaldehyde and its polymer possess antiseptic properties, and a 40 per cent. solution of formaldehyde is now used to a considerable extent, under the name of "formalin," as an antiseptic, and especially as a preservative. Paraldehyde, $(\text{CH}_3\text{CHO})_3$, is a hypnotic, which, although its depressant action upon the heart is less than with chloral, gives rise to irritation and vomiting.

By substituting the hydrogen atoms in acetaldehyde by chlorine their narcotic power is much increased, and in *chloral hydrate*, $\text{CCl}_3 \cdot \text{CHO} \cdot \text{H}_2\text{O}$, a valuable and largely used hypnotic is obtained. As already mentioned, Liebreich was led to the investigation of the physiological properties of this body from a consideration of its decomposition products by means of alkali. Chloroform and sodium formate result, even with extremely dilute alkaline solutions; chloral is soluble and readily absorbed; when absorbed it enters into the blood, which has an alkaline reaction, and there Liebreich expected it to be decomposed into physiologically active chloroform, and practically innocuous sodium formate.

These expectations as to the utility of chloral as a hypnotic have been fully answered, but whether the action is direct or not is somewhat doubtful. Experiments by Hammersten point to a direct action, and although the greater portion of chloral which is absorbed is eliminated in the urine as urochloralic acid, $\text{C}_2\text{H}_5\text{Cl}_3\text{O}_7$, a certain small proportion is not accounted for; and it may be that this fraction plays an important part in the action of the drug, being decomposed, according to Liebreich's view, with the liberation of "nascent" chloroform. One disadvantage, however, accompanies the use of this, as of many simple aldehyde derivatives: it has a depressing action upon the heart, and therefore its application becomes dangerous in all cases of cardiac feebleness. To overcome this objection, Schmiedeberg (1885) suggested the use of *urethane*, ethyl carbanate—

as a hypnotic—a body which he regarded as likely to combine the stimulating action of ammonia with the narcotic effect of an alcohol radical. The therapeutic properties indicated by theory have been realised in this drug, so much so, indeed, that Hübner and Sticker have pointed out the necessity of avoiding large doses (above 2 grms.), owing to the stimulating action of the amido-groups overcoming the narcotic power of the hydrocarbon residue under such conditions, and thus preventing instead of producing sleep. The presence of the carboxyl residue, with the introduction of which a decreased toxicity is always associated, is an additional factor in determining the therapeutic value of chloral hydrate. Binet has recently shown that the hypnotic power of the urethanes increases with the molecular weight of the alkyl radical amongst the lower members, and that by replacing a hydrogen atom in the amido-group by acetyl, the physiological action is preserved whilst the toxic power is lessened.

The knowledge that halogens increase the narcotic effect of aldehydes has led to a further development of Schmiedeberg's ideas in the preparation of *chloral formamide* (chloralimide)—

an aldehyde derivative, in which the hypnotic powers of the aldehyde group are increased by the substitution of chlorine by hydrogen, whilst its depressant action upon the heart is corrected by the presence of the amido-group. Like urethane, it has been found to possess to a large extent the therapeutic properties indicated by theory.

The *ketones*, chemically so closely allied to the aldehydes, also act as narcotics, and Dujardin-Beaumetz has suggested the use of *acetophenone*, $\text{CH}_3 \cdot \text{CO} \cdot \text{C}_6\text{H}_5$ (*hypnone*), as a hypnotic. *Sulphonals*, which belong to the group of aliphatic disulphones, is derived from acetone being obtained by the oxidation of the corresponding mercaptol. The original investigations of Kast on the therapeutic value of sulphonals as a hypnotic have been amply confirmed, and it is now recognised as a safe drug for the production of sleep, and as one free from bad secondary actions. Its reliability is, perhaps, somewhat questioned, marked variations being shown in the time required for its effect to be

produced. A substance boiling at 300°C ., and soluble only in 500 parts of water, will of necessity be only slowly absorbed by the system.

The physiological action is to be traced primarily to the ethyl groups present, and it is immaterial whether these are directly in combination with the methane carbon or not, for sulphonals and "reversed sulphonals" act similarly.

The sulphone with four methyl groups is perfectly inactive, whilst the triethyl- and tetra-ethyl sulphonates are stronger narcotics than sulphonals. *Trional*, which is more soluble than sulphonals (1 : 320), acts more rapidly—

Baumann and Kast regard the SO_2 group as inactive in these compounds, but it is not unlikely that the absence of marked contra-indications with sulphonals are to some extent due to the presence of this radical, for it is well known that the sulphonic acid group decreases the toxicity of aromatic compounds.

Antiseptics.—The majority of the antiseptics are to be found amongst aromatic compounds. *Phenol* has powerful antiseptic properties, but it is also an irritant poison. Its homologues (the *cresols*) are still more powerful antiseptics, but they are less poisonous. *Meta-cresol*—

for instance, which is the most powerful antiseptic of the three isomers, is four times less poisonous than phenol. Many cresol preparations are now employed in antiseptic surgery, such as *creolin*, *lysol*, *solveol*, and *solutol*—more or less impure mixtures prepared from coal-tar—and also pure products, such as Liebreich's "*Tri-cresol*," a mixture of the pure cresols.

By replacing a second hydrogen atom in benzene by hydroxyl, both the antiseptic and the poisonous properties are increased. The extent of the change depends, however, upon the relative position of the hydroxyl groups. In *catechol* the action is most powerful, in *resorcinol* weakest, *quinol* occupying an intermediate position.

By further replacement of hydrogen, the lethal activity may be further increased, *phloroglucinol* being more poisonous than *quinol*, and also more poisonous than its symmetrical isomer *pyrogallol*. The rapidity of action of these drugs is in inverse ratio to their toxic power: phenol acts more quickly than resorcinol, and this than phloroglucinol—an effect said not to depend upon their solubilities, for phenol is the most sparingly soluble of the three (Lauder Brunton). Certainly the reducing actions of these phenols on the blood must be the chief factor in their relative toxic effects and their solubilities, not in water, but in the gastric and pancreatic juices, and especially in the blood—the chief consideration in regard to the rapidity of their action.

The antiseptic power of the halogens is brought out in such organic antiseptics as iodoform, tetra-iodo-pyrrol (iodol) and di-iodo-thiophene. The halogen derivatives of the phenols are more powerful antiseptics than the phenols themselves, as one would naturally expect: at the same time they are less poisonous. Of the *mono-chlorphenols*, the para-compound $\text{C}_6\text{H}_4 \cdot \text{OH} \cdot \text{Cl}$ (1:4) has the most powerful antiseptic properties, whilst tribromophenol—

has, owing to its insolubility, been recommended by Grimm as an intestinal antiseptic.

A study of the changes phenol undergoes on passing through the system has given rise to the preparation of numerous phenol derivatives for therapeutic use. A portion of the phenol absorbed disappears entirely; it is probably oxidised completely to carbon dioxide and water. A second portion is oxidised to dihydroxybenzenes, chiefly quinol, a

third portion combines with glycuronic acid in the system, and a small quantity, especially when large doses are given, appears unchanged in the urine. But the most interesting change from a pharmacological standpoint is the elimination of the remainder of the phenol as an ester of sulphuric acid, *phenyl sulphuric ether*—

the form in which it is always excreted in pathological conditions. Such esters are not poisonous, their salts are readily soluble, and they pass through the system unchanged. Hence the application of salts of phenyl sulphuric acid as antiseptics. The very closely allied phenol-sulphonic acids behave similarly. The antiseptic power of *ortho-phenol sulphonic acid*, $\text{C}_6\text{H}_4(\text{OH})\text{SO}_3\text{OH}$ (1:2), is somewhat less than that of phenol, it is also less toxic and very soluble.

With the view of obtaining more powerful antiseptics, still retaining the advantages of the sulphonic acids, Trommsdorf prepared the so-called *sozo-iolol salts*, the di-iodo-substitution products of para-phenol sulphonic acid. In these compounds the irritant action of the iodo-phenols is attenuated by the presence of the sulphonic acid group. With the exception of the mercury salt, which is of value in syphilitic cases, they are perfectly innocuous and readily soluble. They have no smell—an advantage over iodoform; and since their introduction in 1887, they have been largely used for the most varied antiseptic purposes. From the returns kindly supplied by H. Trommsdorf and Co., the sale of these sozo-iolol preparations has increased from 168 kilos. in 1887, valued at 630*l.*, to 1,152 kilos., in 1895, valued at 1500*l.*

The sodium salt is the most soluble of these compounds (1 to 14 at ordinary temperatures); its composition is represented by the formula—

Di-iodophenol sodium sulphionate.
(Sodium sozo-iolol.)

The naphthols, especially the β compound, are, like the phenols, powerful antiseptics, and the advantageous influence of the sulphonic acid group has been made use of in the preparation of naphthalene derivatives corresponding to the above. *Asaprol*, the name given to the calcium salt of β -naphthol- α -monosulphonic acid—

has been recommended as an antipyretic rather than as an antiseptic—an application due to its non-poisonous character, and also to its passing through the system unchanged. A more interesting instance is the use of the *aluminium salt of β -naphthol disulphonic acid*—

as an antiseptic and astringent.

The objection to the metallic salts employed as astringents is due to their precipitating albumen, and therefore, when applied to an ulcer or other inflamed mucous membrane, of forming an insoluble coating on the surface of the structure, thus preventing the antiseptic from reaching the inflamed parts in the more deeply situated tissues. Aluminium salts possess the property of dissolving in excess of albuminoid secretions, but their tendency to form basic salts again presents the obstacle they are otherwise suited to overcome. This fact led Heinz and Liebrecht to look to the aluminium salts of organic acids as substances likely to possess the advantageous properties of the base without the disadvantage shown by the acetate and other aluminium salts previously employed. In the disulphonic acid of β -naphthol they found an antiseptic without poisonous properties, and its aluminium salt has the penetrating powers

of the base satisfactorily preserved. 40 per cent. aqueous solutions prepared with hot water remain quite clear on cooling, and in the treatment of ulcers and similar wounds it has proved a valuable antiseptic.

In another group of phenol derivatives—the phenol ethers—many interesting examples of the synthesis of physiologically active compounds occur. *Guaiacol* and its derivatives are probably the most important of these. Sahli was the first to recognise that the value of creosote in phthisis was due to the contained guaiacol, and this methyl ether of catechol, $\text{C}_6\text{H}_4(\text{OH})\text{OCH}_3$ (1:2), is now largely used in the treatment of this disease. Guaiacol, like catechol, is a powerful antiseptic, but the contractile action of the latter, and its effect in diminishing the blood pressure are much decreased by replacing the hydroxyl-hydrogen by methyl. The action of guaiacol in phthisis is attributed by Sahli to its effect upon the stomach, as a stomachic, and not to any direct effect of the absorbed guaiacol in the blood upon the tuberculosis bacilli of the lungs. The work of the chemist in this case is an important type, for the practitioner has to thank him for a product of reliable purity, on the action of which he knows he can always depend.

With the view of overcoming the irritant action of guaiacol on the digestive functions, several esters, such as *benzoylguaiacol* (benzosol), $\text{C}_6\text{H}_4(\text{OCH}_3)\text{O} \cdot \text{CO} \cdot \text{C}_6\text{H}_5$, have been prepared. Such bodies prepared on the type of salol, to which I shall presently refer, pass through the stomach unchanged, and undergo decomposition in the intestines. Benzosol acts as an intestinal antiseptic, but is of no value in phthisis—a confirmation of Sahli's view of the action of guaiacol. Of many other esters, *guaiacol carbon* etc—

has proved the most valuable. Although, like the benzoyl ester, it passes through a healthy stomach unchanged, it is said to undergo decomposition there in presence of parasitic bacteria.

What the exact work of guaiacol in phthisis is, appears capable of receiving much elucidation from a comparative study of the actions of guaiacol and of its carbonic ester.

Antipyretics.—Antipyretics, or febrifuges, include those substances which reduce the temperature of the body in fever. They may either lessen the production of heat or increase the loss of heat. The majority of the synthetically prepared antipyretics, in common with quinine, decrease the production of heat. Antipyrine is an exception. According to Gottlieb the production of heat is increased 5–9 per cent., and the loss of heat increased 10–20 per cent.; it therefore reduces the temperature because the increased loss of heat exceeds its increased production.

The commercial success of antipyrine has been followed by a veritable boom in the preparation of antipyretics, but the rush has been too rapid to have been carefully planned, with the result that the lives of many of them have been conspicuously fleeting.

It has been shown by Nencki and Boutmy that the introduction of the carboxyl group into a large variety of aromatic compounds markedly decreases their toxic action. Benzoic acid is much less poisonous than benzene; salicylic acid than phenol. Kolbe was the first to direct attention to the antiseptic and non-poisonous properties of salicylic acid, and Buss subsequently showed that it had a marked and specific antipyretic action in cases of muscular rheumatism. The use of salicylic acid and its salts as anti-rheumatics is well known, but their value for this purpose is seriously diminished by the disturbance of the digestive functions which they may occasion. The esters of salicylic acid, like those of the phenols, pass through the stomach unchanged, and are decomposed in the duodenum by the pancreatic juice and alkali into salicylic acid and the phenol with which they are combined, e.g.:—

Salol the phenol ester of salicylic acid—

has proved to be the most valuable of these compounds. As an anti-rheumatic it claims special advantages over salicylic acid in all cases of weak digestions, but it is as an intestinal antiseptic that it has proved most useful. Such a chemical combination of physiologically active substances has often been repeated, but not always with success. Unless the physiological action of such compounds can be localised, their resultant effect, additive or the reverse, is mere chance.

Whilst the replacement of a hydrogen atom in the aromatic hydrocarbons by the hydroxy group increases their antiseptic properties, an increase in their antipyretic powers accompanies the introduction of the amido group. Aniline has a paralysing effect on both muscle and nerves; it has a powerful toxic action, and is eliminated in the urine—partly unchanged and partly as para-amido-phenol-sulphuric ester.

In *acetanilide* (antifebrine), $C_6H_5.NH.CO.CH_3$, this toxic effect is much decreased whilst the antipyretic properties remain. It is a widely-used antipyretic, largely on account of its low price, but bad secondary symptoms are said to occur unless judgment be exercised in its application. Its homologues, the *acet-toluides*—

do not all preserve this antipyretic action: the 1:4 compound is quite inactive, the 1:2 compound has no antipyretic action, whilst the 1:3 isomer is the only one that preserves the antipyretic action of acetanilide. When, however, the methyl group replaces the second amido-hydrogen, instead of a hydrogen atom in the ring, an interesting therapeutic change has been observed by Dujardin-Beaumetz and Bardet. *Acet-methyl anilide* (Exalgine), $C_6H_3.N(CH_3).CO.CH_3$, is a valuable analgesic; its antipyretic action is much less than that of acetanilide, in fact, it only appears when almost toxic doses are given (Fraser).

Although both aniline and phenol are powerful poisons, the amido-phenols are comparatively innocuous; from chemical considerations such a mutual influence of the substituting groups would be expected. By the introduction of alkyl- or acid aliphatic radicals into 1:4-amido-phenol a number of useful antipyretics have been prepared, of which *phenacetine* and *lactophenine* are types. The carboxylic acid of phenacetine—

has been shown by Nencki and Boutmy to pass unchanged through the body—a point of interest, because in *phenocoll* a methyl hydrogen of the acetyl group is replaced by the amido group, whilst in *thermodine* an added carboxyl group is present. This latter, which is really a urethane derivative, is regarded by v. Mering as the best antipyretic of the amido-phenol group.

The steps that have guided the chemist to the preparation of these compounds are full of interest, and I regret that the time at my disposal does not permit me to detail them to you.

One derivative of para-amido-phenol deserves notice from a different standpoint—its condensation product with salicylaldehyde. This substance was introduced by Jaquet in 1893 as an anti-rheumatic, under the name of "*Malakine*." It is insoluble in water, but is decomposed by very dilute acids into para-phenetidine and salicylaldehyde.

This decomposition Jaquet regarded as likely to be effected by the stomach acids, and that the liberated aldehyde, oxidised to salicylic acid in the tissues of the body, would act as a powerful anti-rheumatic. Practice has justified this view. *Malakine* is a useful anti-rheumatic possessing certain advantages over salicylic acid, although whether as generally useful as the latter is somewhat questioned.

Antipyretics derived from Para-amido-phenol.

(*Phenocoll hydrochloride*.)

Phenacetine carboxylic ester.
(*Thermodine*.)

In quite another group of bodies an interesting series of inquiries have led to the preparation of kairine, and indirectly to the recognition of the therapeutic value of antipyrine. Few substances are of more importance in medicine than the natural alkaloids, a class of nitrogenous substances characterised by their basic properties, and which until recently have successfully resisted the onslaught of the synthetical chemist.

In the various groups of the alkaloids a similarity in physiological action is to be traced, and it is amongst these very compounds that the earliest experiments on the relation of chemical constitution to physiological action were carried out by Crum Brown and Frazer in 1869. It is well known that a pyridine, quinoline, or isoquinoline ring forms an essential part of the molecule of many of the alkaloids, many derivatives of these bases having been obtained as their decomposition products. This relationship has been further borne out by a study of the physiological properties of compounds derived especially from quinoline.

Foremost amongst these substances stands *kairine*, which, although to-day eclipsed by newer antipyretics, has an exceptionally interesting history, on account of the complete nature of the researches of Otto Fischer and Filehne on this and closely allied bodies.

Quinoline itself possesses powerful antiseptic and slight antipyretic properties, but it causes so many unpleasant secondary reactions in the system that it is of very little value as a febrifuge.

By substituting a hydrogen atom by hydroxyl, 1-*hydroxy-quinoline* is obtained, which, together with its methyl ether and their respective tetrahydrides, has an antipyretic action akin to that of quinine, but which, owing to the tendency it possesses of decomposing the albumen, is unsuited for practical application.

The possible value of these artificially prepared drugs was clear to Fischer and Filehne, and they sought at once to eliminate the injurious secondary effects which accompanied their use. From chemical considerations they regarded the instability of the imido group, $=NH$, as the probable cause of the injurious effects referred to, and with the object of giving increased stability to the molecule they replaced the imido-hydrogen by an alkyl, *kairine* being the resulting product. The hydrochloride of this base was successfully employed as an antipyretic for several years after its discovery in 1883, in fact, until driven from the field by its own children.

Numerous derivatives of kairine have since been prepared—*Thalline* (3-methoxy-tetra-hydroquinoline), *Kairine* (N-methyl-tetra-hydroquinoline), and others. They all resemble kairine in their action and differ essentially in the time during which the antipyretic effect lasts. That of 1-ethoxy-tetra-hydro-N-methyl-quinoline lasts the longest.

By the action of ethylene-dibromide on 1-hydroxy-tetra-hydroquinoline a substance is obtained in which the two reduced quinoline rings are united by the divalent residue, $-\text{CH}_2-\text{CH}_2-$. It is not improbable that the cinchona alkaloids contain a quinoline ring, united to a second reduced quinoline ring, and hence considerable interest attaches to the physiological action of this product 1-hydroxy-tetra-hydro-ethylene-quinoline. It does act as an antipyretic, but, owing most likely to its feebly basic properties, its action is considerably weaker than that of kairine.

In looking back on the work done amongst this group of bodies, I should remind you that the first investigations on their physiological action were carried out by McKendrick and Dewar in 1874 (*Proc. Roy. Soc.* 1874, 22, 432), and this at a time when the synthetical methods now used for the preparation of quinoline and pyridine compounds were unknown.

One point of interesting comparison between these drugs and quinine is that the antipyretic action of the latter in malaria and other intermittent fevers is not shared by the artificially prepared bodies. There must be some portion of the quinine molecule to which this special action is to be traced. Chemically and physiologically a portion of the constitution of the complex quinine molecule has been revealed; such combined efforts will best lead to its complete elucidation.

Antipyrine, discovered by Knorr in 1884, has had, as I need hardly tell you, a phenomenal career. As an antipyretic and as an anti-rheumatic in whooping cough and in cramp it has proved of immense value, whilst as a nerve tonic it is most widely, but not always wisely used, and too often without medical advice.

The money value of this drug consumed to-day is almost one-half of the total value of the newer synthetical remedies, and I was indeed surprised to learn from Dr. G. von Brünig that in addition to his own works, where antipyrine was first manufactured, there are now no less than 12 others where it and its derivatives are prepared.

Knorr first regarded antipyrine as a quinine derivative, and as such it bore sufficient analogy to the physiologically active quinoline compounds prepared by Otto Fischer in the same laboratory as to suggest the investigation of its physiological properties—a work first undertaken by Filchne. More recent investigations have led Knorr to assign a different constitutional formula to antipyrine—that of a substituted pyrazolone; but it was its supposed relationship to kairine that first led to its being examined by the physiologist.

Several substances constitutionally allied to antipyrine are known to-day, which share its antipyretic action, but none of which have exceeded or even approached it in general reliability or utility.

(Antipyrine.)

Of other cyclic nitrogen compounds *piperazine* and *lysine*, uric acid solvents, and therefore of value in the treatment of stone and other conditions associated with a separation of uric acid in the system, and the remarkable stomachic *Orexine*, prepared by Paul, deserve mention. This last, according to the investigations of Penzoldt, has the property of stimulating the feeling of hunger, but the earlier experiments made with the hydrochloride of the base were found to give rise to irritation in the stomach. The free base has since been recommended, which, despite its insolubility, satisfactorily retains the therapeutic value of its salt.

I have attempted to bring before you some of the most typical examples of the manner in which the chemist and physiologist have mutually worked and helped in the preparation of therapeutically valuable products. There is much of the ground I have left untouched, but I hope what I have said is sufficient to show what a wealth of scientific material has been built up on the foundations laid by Crum Brown, Frazer, Liebreich, and Lauder Brunton. Most of this work has a life-history of little more than 15 years. No words are needed to accentuate the fact that it is but in its infancy, and that the combined labours of the chemist and physiologist will carry it far beyond its present limitations.

Interesting as this inquiry is to the pure scientist, I feel some need to justify my having chosen it as the subject for an address to a Society of Chemical Industry.

You may naturally ask, is the preparation of these drugs in itself worthy of rank as an important chemical industry,

or is their manufacture more or less casual in different works, according as raw materials or other conditions favour their production?

The fact that 13 manufacturers engage in the preparation of antipyrine and its derivatives is a partial answer to the question. I have attempted to answer it also from another standpoint.

The accompanying table shows the quantities of the most important of these new drugs used in the chief hospitals in the kingdom during the year 1895. There is every reason to suppose that such institutions are strictly

economical in the purchase and use of their medicines, and therefore that the returns given can be taken as a reliable register of the value of these newer preparations.

The total annual value of these seven products, as used in 17 hospitals containing 6,668 beds, is almost 600*l*. This figure applied proportionately to all the hospitals in the kingdom containing over 80 beds represents an annual value of nearly 3,000*l*.

In these figures I have purposely omitted salicylic acid and its salts, which have a very extended use, for they are hardly to be regarded as amongst the newer drugs.

HOSPITAL.	Number of Beds.	Quantities of Drugs used in 1895 (in ounces).						
		Antipyrine.	Antifebrine.	Guaiacol Carbonate.	Phenacetine.	Piperazine.	Salol.	Sulphonal.

Value	25 <i>l</i> .	1 <i>l</i> . 10 <i>s</i> .	12 <i>s</i> .	5 <i>l</i> .	31 <i>l</i> . 10 <i>s</i> .	12 <i>l</i> .	33 <i>l</i> .

Total value 598*l*. Hospitals contain 6,668 beds.

Total hospital accommodation in United Kingdom (excluding hospitals with less than 80 beds) 32,000 beds.

Total proportional value of above 7 drugs used in 1895, £2,870.

Whilst a sum of 3,000*l*. is expended by the hospitals on seven of these products, a far larger sum must represent their consumption through private practice.

From returns kindly supplied to me by the chief wholesale and retail chemists in Liverpool, I find that in this centre alone the value of these seven products sold is quite 5,000*l*. annually, and I believe I am well within the mark in estimating the total value for the United Kingdom from all sources at 250,000*l*. I do not regard these figures as anything more than the merest approximations, but I do not think they err on the side of excess, for the newer products so largely used in anti-septic surgery are not included at all.

Products which in this country alone realise annually a quarter of a million should, I think, merit the attention of the manufacturing chemist.

Paracelsus said the "object of the chemist is to make medicines, 'not to make gold'; it has been reserved for later generations to see the possibility of their combination. But this combination is not effected here. With the exception of acetanilide and some salol, the whole of the drugs are "made in Germany." And why; why does not this 250,000*l*. a year stay in this country?

I have already trespassed long enough upon your time, and do not propose to do more than refer you to a point in the address of the ex-president of the Society—a point of great importance to my mind, namely, the disadvantages under which industrial organic chemistry must labour in this country until the Government finds means for allowing the use of duty-free alcohol denatured according to the uses made of it, as is done abroad.

Mr. Tyrer's summary of this subject (this Journal, 1896, p. 496) is full of interest, and I am very glad to be able to add that the Advisory Committee recently constituted by the Council, on the suggestion of Mr. Tyrer, is at present giving the matter its most careful consideration. That this recently appointed committee has already taken in hand so important a subject is a matter for sincere congratulation. No more practical proof could be desired to show that the Council of the Society truly recognises the

interests of manufacturers, and most heartily can I wish the committee all success in its work.

Granted this equality with other nations, and a more thorough appreciation and practical recognition of the value of organic chemistry in works—for it is in the actual preparation of these products that the powers of the well-trained chemist and not the workman, despite all the technical classes in the world, are required,—granted these points, which the present condition of our industries should encourage us to secure, there is no valid reason why the manufacture of drugs and other closely allied industries should not meet with the same commercial success in this country which has characterised their development abroad.

In conclusion, I wish to express my best thanks to Prof. Oscar Liebreich for his kindness in directing my attention to much of the published work on this subject, to the dispensers of the hospitals who have kindly supplied me with the statistics recorded, and especially to the following firms, through whose goodwill and generosity I am able to show you an exceptionally complete collection of the newer drugs:—Chemische Fabrik von Heyden, Radebeul, Dresden; Farbenfabriken vormals Fr. Bayer, Elberfeld; C. F. Boehringer und Söhne, Waldhof; Farbwerke vorm. Meister, Lucius, and Bräuning, Höchst a. Main; Dr. W. Kalle and Co., Bielefeld; H. Trommsdorff and Co., Erfurt; and Chemische Fabrik auf Actien vorm. E. Schering, Berlin.

DISCUSSION.

Mr. EUSTACE CARLY proposed a vote of thanks to the Chairman for his interesting address.

Prof. CAMPBELL BROWN, in seconding the vote of thanks, said that he thought there must be amongst them all a feeling of amazement, not unminged with shame, that the magnificent array of specimens shown was not manufactured in this country, which produced such a large proportion of the raw material (coal-tar), and in which the first scientific investigation on the subject of the address had been carried out. Dr. Kohn had mentioned that the want of duty-free alcohol in this country had a great deal to do with it, and

that was the fault of the Government. The real fault, however, lay with the manufacturers and the people of this country, who were not sufficiently determined to have these things made in this country, and to compel the Government to give them duty-free alcohol. Why did not manufacturers care to manufacture those substances? Was not the reason something of this kind? Capitalists here preferred to manufacture compounds of which they could sell thousands of tons, and were not much interested in a substance which at first realised a sale of 600*l.*, rising in some years to 6,000*l.* But was that wise? He thought not. If they were to multiply the 600*l.* and the 6,000*l.* by one hundred different substances, the result would be worth the consideration of the large capitalists.

Dr. HURTER pointed out that in this country we had a liberal patent law, which allowed every foreigner to patent an article without compelling him to come into this country to manufacture it. The patent law of this country protected the foreign industry and did not promote the home one. If one of the younger chemists were to bring forward a new article, which could be protected, they might succeed with that, but to attempt to compete in the old articles with manufacturers who had years of experience, would be throwing money away. That was quite as potent a reason for the absence of industrial organic chemistry, of the kind referred to, as the duty on alcohol.

Prof. CURRIE remarked that, although great progress had been due to the introduction of many of the drugs spoken of, yet one hesitated to accept everything that was adduced as proof concerning one or other of these bodies. He instanced a case in which very beneficial effects were stated to be due to piperazine—lauded as an excellent solvent of uric acid. In a case which had come under his notice, a calculus was discharged shortly after administration of piperazine, and the result was put down to piperazine, until it was ascertained that the calculus was an oxalate of calcium (not uric acid at all)—a substance on which piperazine has no action. He had himself found the action of piperazine, when allowed to drip on a uric acid calculus, no greater than that of water. But how was it that such a substance as, for instance, sulphonal, was so uncertain in its action? Its insolubility would not explain this; it sometimes acted extremely well. The answer to this question was very much needed. They often felt, when standing at the bedside of a patient suffering from heart disease, for example, that their hands were tied, for they did not dare to obtain sleep for the patient, owing to the possibility of ill-effects from the hypnotic. It was required to know the personal factor that would tend to make these drugs more active or inactive.

Dr. KOUX, in reply, expressed his hearty concurrence in the importance of the point raised by Dr. Hurter in reference to the disadvantageous effects of the law relating to the granting of patents without insisting upon manufacture. In regard to the therapeutic effect of piperazine, he had found so many conflicting opinions that he had omitted detailed considerations, but he had not heard its power of dissolving uric acid outside the system questioned. The opinions expressed differed more in regard to its solvent action in the system and especially in presence of urine.

The personal element referred to by Prof. Carter was one of the greatest practical importance, but he felt that it was to the pharmacologist rather than to the chemist that they must look for its solution.

SESSION 1895-97.

December 1, 1894:

- (1) Dr. Stevenson Macadam. "On Safe and Unsafe Mineral Oils for Lighting and Heating Purposes."
- (2) Dr. J. Lawkowitzsch. "Contributions to the Analysis of Fats."

Meeting held on Friday, November 6th, 1896.

CHAIRMAN'S ADDRESS.

It is not very difficult to find a subject to talk about in the domain of industrial chemistry, but to say beforehand that any selection of material would be universally interesting, is to say a great deal. The matters to which I desire to call your attention this evening scarcely come within the pale of laboratory practice, but that you will agree with me in saying they have universal interest, I do not doubt in the smallest degree. It is pardonable, I think, to allude to the present crisis in the commercial departments of the alkali trade and in those of heavy chemicals generally; and though not prescribing for the maladies from which we seem suffering, I hope it may lead those who are responsible for the present state of affairs to look at the subject in a reasonable light and to deal with the question in a statesmanlike manner.

In my last address to you I expressed my fears that a crisis was impending in the caustic-soda industry, and that fear has been realised. At that date 7*l.* 15*s.* could be realised for a ton of 70 per cent. caustic, but to-day caustic-soda of 70 per cent., made from ammonia alkali, can and has been purchased at 6*l.* 2*s.* 6*d.* per ton; and what is still worse, 77 per cent. has been offered *pro rata*, the difference of over 2*l.* per ton for higher-strength caustic having now practically disappeared. And this is not all; the value of salt-cake has declined from 1*l.* 7*s.* 6*d.* in January of this year to less than 18*s.* at the present moment, and bleach has receded from 7*l.* to 6*l.*, packed in softwood casks and placed free on rails at the makers' works.

The exact situation of the heavy chemicals trade is rather an intricate one to follow, or—perhaps it would be more correct to say—has been made intricate from the many different prices quoted in various places for the same product; but when the quoted values are stripped of the extra-manufacturing expenses, so as to level the products down to a "packed" and f.o.r. price, we have a set of figures of unusual interest to the trade which go to show that we are again approaching a like period to that when, in 1890, the leading heavy chemicals manufacturers banded themselves together to federate their works and to form one huge confederation therefrom.

In order to set forth clearly the changes that have taken place, the following table has been prepared, showing the values realised for each article enumerated in the past nine Januaries:—

PRICES OF ALKALI PRODUCTS IN JANUARY OF EACH YEAR.

	70 Caustic.			Bicarb.			58 Alkali.			Bleach.			Soda Crystals.			Salt- Cake.		
	£	s.	d.	£	s.	d.	£	s.	d.	£	s.	d.	£	s.	d.	£	s.	d.
1888	6	18	9	5	15	0	4	12	6	7	11	3	2	10	0	1	2	0
1889	7	0	0	4	15	0	5	0	0	7	5	0	2	7	6	1	1	0
1890	7	17	6	5	0	0	5	12	6	5	5	0	2	12	0	1	6	0
1891	15	5	0	7	5	0	6	12	6	6	12	6	3	7	6	2	0	0
1892	14	5	0	6	15	0	6	7	6	7	10	0	3	9	0	1	17	6
1893	9	10	0	6	10	0	5	7	6	7	10	0	3	2	6	1	10	0
1894	9	5	0	6	15	0	4	2	6	7	15	0	3	0	0	1	0	0
1895	7	17	6	5	12	6	4	0	0	7	5	0	2	5	0	0	17	6
1896	7	10	0	6	10	0	3	15	0	7	0	0	2	2	6	1	7	6
To-day	6	2	6	6	10	0	2	5	0	6	0	0	2	0	0	1	0	0

The year of lowest prices in 70 per cent. caustic was 1888, in which it was sold at 16*s.* 3*d.* more than can be obtained to-day; the year of lowest-price bleach was in

1890, when the price was 5 guineas, but the year of lowest-price salt-cake was not reached until the end of 1894, and lasted a long way into 1895. For this year (1895) 17s. 6d. is the quoted value, but that is quite a high figure, for very large quantities changed hands at as low as 12s. 6d. per ton at the maker's works. This, no doubt, was very encouraging to glass-makers and others who used salt-cake, and the low prices of caustic soda and bleach in their respective years were perhaps of assistance to the paper makers and bleachers; but we may pause to inquire whom these blessings have permanently benefited. The following table will show the loss of revenue to the alkali maker by the fall in prices from the normal, and are based upon the output from a works consuming 160 tons per week of 50 per cent. pyrites working by the best-known methods.

I have estimated that such a works as above will produce 200 tons weekly of sulphuric acid of 1.615 sp. gr., and this will produce not less than 200 tons of 97 per cent. salt-cake. Now, reckoning that 40 cwt. of salt-cake will make 1 ton of 70 per cent. caustic (a very fair average production), 100 tons of 70 per cent. caustic should be produced in such a works per week. In a works of this size the wages will not be less than 250*l.* weekly, including tradesmen and labourers. The table has been constructed on the foregoing basis, taken in conjunction with the values of Table I.

WORKS MAKING AND SELLING BLEACH AND CAUSTIC (70 PER CENT.), OR BLEACH AND SALT-CAKE ONLY.

TABLE II.

	Revenue from Bleach.	Revenue from Caustic.	Total.	Revenue from Bleach.	Revenue from Salt-Cake.	Total.
	£	£	£	£	£	£
1888	760	605	1,455	760	220	980
1889	725	700	1,425	725	210	935
1890	525	799	1,315	525	200	725
1891	660	1,125	1,785	660	400	1,060
1892	750	1,025	1,775	750	374	1,124
1893	750	950	1,700	750	300	1,050
1894	775	925	1,700	775	200	975
1895	725	75	1,510	725	174	899
1896	700	750	1,450	700	274	974
..	640	680	1,290	600	200	800

The bleach revenue of the foregoing table is based on a production of a ton of bleach from 36 cwt. of salt by the Davis-Weldon process, which, I am assured, has been obtained in at least one works, though I am of opinion that such a yield is an abnormal one; but still it serves as an easy and excellent mode of comparison, and will do just as well for our purpose as the more common and average production of 1 ton of bleach from 40 cwt. of salt.

A glance at the table (II.) will show us that the total weekly revenue in making bleach and caustic soda, until quite recently, reached its lowest point in 1890, after which there were four years of plenty, in comparison with what had gone before. The years 1891—1894 inclusive were fair years, but I think I am correct in stating that the profits of those years did not give the shareholders of the various manufacturing concerns more than the moiety of a parliamentary dividend as measured by the gasworks standard. To-day the total revenue from these sources in such a works as we have considered is 115*l.* per week lower than it has ever been during the decade, and 585*l.* less per week than when a small dividend was paid.

Turning again to a similar works, wherein only bleach and salt-cake are made and sold, the lowest total revenue from these sources was also in 1890, it having declined to 785*l.* weekly. In 1891 there was an increase of 275*l.* weekly, which by January 1892 had increased to 339*l.*, from which point it has steadily declined, until to-day it stands at practically the same figure as in 1890.

Some of you may be tempted to exclaim: "What a profit must have been made in 1891—1894, with such an *excess* of revenue over what can be obtained to-day!" or, arguing conversely, what a loss must be going on to-day when the revenue is so much *less* than it was in the years 1891—

1894! Neither proposition is correct. The old Weldon process, as it was worked in 1887, is obsolete. The profit (if any), or let us say the reduction in the cost of production, has been brought about by the lessened prices of the raw materials used in manufacture, by the sandwicheing in of more economical processes, by which less is made of that product (salt-cake) now produced and sold at an absolute loss, and lastly by the reduction in wages, whereby many workmen have been thrown out of employment, and the remainder reduced to a bare living wage. As a result, who has benefited? Is it St. Helens, which has almost become a barren wilderness? Or Widnes, or Glasgow, or the Tyneside? Are the workmen happy and in constant employment? Or are the shareholders in these concerns in the receipt of enormous dividends? If none of these blessings have come to the share of the chemical trade, to whom have they fallen?

I think it can be shown that a works such as I have already described, simply making and selling bleach and salt-cake, producing that bleach by the Weldon process, cannot make both ends meet by reason of the enormous loss on salt-cake. As before mentioned, salt-cake has been sold at less than 13s. per ton f.o.b. at the maker's works, whereas it could not be manufactured for less than 33s., leaving the general expenses of the establishment entirely out of consideration; and as at least 2 tons of salt-cake are produced for every ton of bleach made (in some cases considerably more), it seems to me to be utter folly to go on producing it in former quantities. But I believe things are on the change so far as this manufacture is concerned, and those who have so far secured forward supplies of salt-cake at low rates are to be congratulated on their foresight.

A change for the better must come, and I believe is much nearer than some suppose. The change from the Weldon to the Deacon-Blaschke process has been rapidly effected in many of the old works, and this has wonderfully restricted the production of salt-cake. The amelioration which this has brought about has been checked, however, by the diminished consumption for caustic making which has followed from caustic soda being made from ammonia-soda-ash, as it now is in large quantities. If there has been an over-production in the Leblanc soda industry, there has been also an over-production in the ammonia-soda manufacture; and the limit of sales having so far been reached for carbonate of soda, the ammonia-soda works have had to turn their attention to the production of alkali in other forms, one school causticising the carbonate with lime, the other school preferring to use oxide of iron. I do not believe, in the long run, there is much to choose from in these two processes, and no doubt they will hang over the line together like Kilkenny cats; but the position of the trade is certainly not calculated to induce new capitalists to enter the arena. But new processes have entered the field, and, judging from advertisements in the trade journals, there are partisans even yet of the older processes; though anyone acquainted with the subject must know that the ordinary alkali trade, with high-strength alkali at 2*l.* 5s. per ton f.o.b., bleach at 6*l.*, and salt-cake at 18s., is not change for a shilling.

Works managers who have only had the opportunity of looking into the manufacturing side of things, and perhaps even of but one process of an establishment, are sadly prone to neglect the general expenses of an undertaking, and in this way the costs of production emanating from such sources are usually sadly too low. The office expenses, the laboratory charges (for these works cannot be carried on with the rule-of-thumb supervision of 30 years ago), and the sundry expenses of the estate, are no small items; yet I have an estimate before me, prepared by a professedly well-informed man, in which none of these items appear. It is, in my opinion, these things that have wrought so much injury to the alkali trade.

But the chemical trade is not alone in its depression. The agricultural interest has, according to common report, been so depressed as to call forth parliamentary treatment and aid. A few moments ago, in speaking of the chemical depression, I asked: "Who has benefited by the low prices?" Has the farmer benefited? He has been able to purchase his nitrate of soda and sulphate of ammonia at prices never

heard of before. Sulphate of ammonia, which was 23*l.* per ton in 1879, can now be had for 7*l.* 2*s.* 6*d.*, and even less, and nitrate of soda has this year touched the lowest price on record; superphosphate has been cheap, and yet the farmer is supposed to have suffered so much as to call for Government reduction in his taxes. But how do things really stand? A farmer pays, say, 30*s.* per acre for the land he tills, and on a 100-acre farm will probably be called upon to pay 22*l.* a year in taxes; at 25 years' purchase this will give the value of the 100 acres as 5,500*l.* Now, supposing this 100 acres to be occupied by a manufacturing concern, directly the landowner is approached for the purchase of such a plot, his idea of its value rises considerably; his 37*l.* 10*s.* or 40*l.* an acre becomes 250*l.* or 300*l.* an acre; and, though he will probably net 25,000*l.* for the plot, which before was practically unsaleable at 40*l.* an acre, he makes no provision out of the fund for the protection of the other tenants of the estate. What does he care about them so long as he can sell his land at such fancy prices? A manufacturing firm occupying such a plot may spend a quarter of a million of money in developing it; the works may earn no dividend, owing to depression of trade; still the amount such a firm would pay in rates would be about, say, 3000*l.*, as compared with the 22*l.* paid by the tenant of the land who happened to be a farmer. Under such conditions as these I think you will all agree with me that it was a little out of place to single out the agricultural interest for special consideration by Act of Parliament.

The chemical trade is one that has been specially harassed—by Acts of Parliament, provisional orders, river inspectors, nuisance inspectors, medical officers of health, factory inspectors, and I wot not more. I say harassed advisedly, but I do not wish to imply by any means that the inspectors of this parliamentary band have been the delinquents. The harassing has been done by those busy-bodies who, outside the camp, fancy they know everything within it, and many are the bogies they have conjured up and have endeavoured to foist on a sensitive public as to the dangers and unhealthiness of the chemical trades. From the five-and-twenty years of experience I have had in the manufacture of many kinds of chemicals, I can conscientiously say that the men employed in the chemical trade are, for physique and general healthiness, equal to, even if they do not surpass, any other trade with which I have been brought in contact.

While on this subject I should like to say a few words upon "inspection." I do not mean inspection under any one particular Act of Parliament, but inspection generally. I believe I am not alone in the opinion that all inspection of whatever kind should be centralised in some Government Department, and that no more duties of this kind should be entrusted to local authorities. As an old inspector of the Local Government Board, and having a district that embraced nearly one-half of England, I may be accused of having some bias towards this method of administering Acts of Parliament; but on my tours of inspection I had ample opportunity of seeing the immense amount of damage done to local industries by petty and ineffective interference from the local authorities. In fact I can go as far as to say that of the many complaints it was my duty to investigate, there did not exist one single one that was not traced to personal jealousy, to municipal bickerings, or to political differences.

It will not be "telling tales out of school" if I recount to you a few of my experiences in this direction.

One instance. A plumber in business in a small town in the South of England persistently complained of the damage done to his garden by the fumes from a certain chemical works more than half a mile away. Many visits were made to this works, but everything was always found in order, and, moreover, I could never trace any damage to the complainant's garden. So after many investigations I decided to ask the Chief Inspector to go down with me, and he, after careful examination of every point, came to the conclusion that there was no damage going on, but that some other motive was at the root of these persistent complaints. The result of further investigations showed that the complainant was at one time employed by the works in question to do all the necessary repairs, but the management, finding this to cost them more than it would cost to keep a resident

plumber, made the change, to the discomfiture of our worthy friend, who was reported to have said that "he would have his knife into the works for throwing him overboard."

To take another case. The owner of a chemical works in a large town had a near relative as next-door neighbour, who made many complaints of these works—complaints which could not be traced to any substantial foundation. I placed myself at the disposal of the complainant to send for me by telegraph whenever the nuisance appeared. The eventful day arrived; I duly received a telegram: "Frightful smell; come at once," and I posted off in hot haste by the first express. The first thing to do was to visit the complainant, who told me direful tales about the gases which had come over that morning, and directed me to a worthy couple who lived on the opposite side of the road, who, on being seen, declared "that very morning the stink was so bad as to make them vomit up their breakfast." Armed with this information, I next visited the works, and much to my surprise found all stopped. There was one old man as caretaker, who told me they had not had fire to the steam boilers for over a week, and that nothing had come in or gone out of the gates, nor had work of any kind been done in the meantime—a statement confirmed by the proprietors and managers, and verified by the books of the firm.

Yet another instance. In another manufacturing town complaints were received persistently from one resident over a period of three years, and every attention was given to his letters. The chemical works selected for his attack were not the nearest to him, but for some reason or other the owners were specially objectionable to the complainant. It was pointed out to him that the works he complained of were in excellent order and excellently managed, but no argument would convince him that he was not undergoing loss of health from the close proximity of these works. There were other features in this case which I cannot disclose without furnishing a clue to the identity of the parties. Suffice it to say that I was so sure there was a motive in this systematic persecution that I determined to root this up also. It was found on inquiry that the late owner of the works had lent the complainant a considerable sum of money from the coffers of the firm, and the new owners having discovered this applied for repayment. It was a bad day's work for them, as from this time the borrower never failed to find the works a nuisance.

Now in each of the foregoing instances the men who so bitterly complained of their neighbours' doings were members of the local governing body, and they thus brought extra pressure to bear upon those they were anxious to consider as offenders; and there is no doubt that they did exercise a great deal of influence over their colleagues. The action of the majority of these local bodies towards manufacturing establishments generally does not inspire any student of the subject with confidence that fresh powers would be used with circumspection, and in this opinion I am strengthened by looking back at the records of local authorities in their attempts at smoke prevention.

Had the attempts to minimise the production of smoke been made by some Government Department specially charged with this specific object, and had the administration proceeded on the lines of the Alkali Acts, I verily believe we should have reached the age of smokeless fires long ago; so that I think it does not point to very great perspicacity on the part of our legislators and administrators of the law not to have discovered long before this that amelioration is not to be brought about by persistently hounding manufacturers before a bench of local magistrates who know nothing about these things. My impression is that manufacturers generally, and especially those who have to use furnaces other than steam-boiler furnaces, were very much to blame in allowing the smoke clauses of the Public Health Act to pass into law without forcing those who drafted the Bill to put their definitions into a more definite shape.

The smoke from steam boilers can be easily minimised and even reduced to *nil*. I have often pointed out how this can be done; but there are many process furnaces which in the present state of our knowledge cannot be made smokeless in all stages of the heating process and yet our

magistrates do not consider these things, but say they are sorry they have no alternative but to fine any offender brought before them on the *ipse dixit* of the nuisance inspector. It is quite sufficient for this man to go into court and, without any corroboration of his story, to secure the conviction of a score of manufacturers who, in the present state of trade, have quite enough to do to keep their heads above water, without spending their time in hanging for hours about a police court waiting for their cases to come on.

Do not imagine for one moment I am arguing for the continuance of the black smoke nuisance, but I say, as I have often said before, that if all the tall-chimney smoke was abolished to-day, the Manchester fogs would still be as bad as ever. I have often pointed out that our fogs are caused solely by the domestic smoke, and that will never be abolished until domestic smoke is brought under police regulations, as it is in many continental cities. To have domestic smoke under police supervision would no doubt be unpalatable to many of our citizens; but if it be so, let them cease to rail against those who are no parties to fog production. In many continental cities the combustion of bituminous coal is prohibited, and I see no reason why the same regulations should not be put in force here.

From steam boilers there should not be any black smoke, but as to its suppression from certain furnaces, I say most decidedly that the present means are ineffective, and that before any real good can be done, some radical change must be made. Take Manchester and Salford for instance: they have for many years systematically harassed all the manufacturers in the city, and in some cases have driven them out of it, yet the atmosphere of Manchester and Salford is as filthy as ever—some say even worse.

Second to the method of constituting a Government Department to take charge of this smoke-abatement question, I believe it would be better than the present system if every large corporation, or a number of them, appointed a man of high technical ability, and having a long practical acquaintance with many various processes, to whom all the complaints of the smoke inspector should be submitted. Let him then make inquiries into the why and wherefore of each case, and if he, after full investigation, advised a prosecution, it would more likely turn out to be a bad case needing a drastic remedy, than what we find under the present system.

Let us now turn our attention to another public question which has been badly treated in the past: I refer to the sewage-purification schemes which have cost local authorities so much money and anxiety, and which is further intimately connected with the pollution of our rivers. When one considers the enormous sums that have been spent upon sewage-purification schemes during the past quarter of a century, and the little good that has resulted therefrom, and the few reliable statistics available for comparison, we are sorely tempted to inquire whether this subject has been attacked in the right way. How many times have our large municipalities changed their "systems," and perhaps made a retrograde movement with every alteration instead of a progression? Who is to blame for this? Is not the true solution to be found in a letter sent by a certain corporation to the Mersey and Irwell Joint Committee only so lately as last month. The letter says: "We could not proceed with the work, owing to the change of surveyors; the new surveyor was not in accord with what his predecessor had done, and this, together with the change in the composition of the Sanitary Committee, has delayed the work; and, moreover, the Committee as now constituted is anxious to visit other works to see what is being done in them." All of you know well enough, without my telling you, of what value the opinion of such a committee (none of whom perhaps have had a technical training) is likely to be, and yet these are the people to whom a constituency entrusts the selection and carrying out of a highly technical problem, and who more often than not consult only their own peculiar fancies. I have had some peculiar experiences in this direction, and it is now long since I renounced the sewage problem from a business point of view as being a too delusive *ignis fatuus* to follow. It is an industry that has never tempted the right kind of industrial chemists within

its portals, and has therefore suffered. The man now who attempts to treat sewage generally evolves his process first and learns his chemistry afterwards, and not infrequently at the expense of those who expect the return of good drinking water from the sewage meted out to him to purify. There are possibilities in everything, but it does not aid in the solution of the problem to exact guarantees from a contractor he is never likely to perform; it may ruin him both in reputation and financially, but we are no nearer finally. I mention this more particularly as a case was recently brought before my notice in which a contractor had offered to purify the sewage of a large corporation at a certain price per million gallons, and offering to conform to a certain standard of purity in the effluent. I pointed out the standard was impossible of attainment in our present state of knowledge, but the reply I received was: "What does it matter to us so long as the responsibility is off our shoulders?" Is this the way to look at a problem of this kind? I say most decidedly not.

Now let us turn to the subject from another point of view,—that of a river conservator's. Is it not a wrong method to exact maximum results in purification before at least one half of the works in operation can be shown to have attained such a degree of perfection? I now specially allude to the action of the Mersey and Irwell Joint Committee in their dealings with the sewage polluters of their watershed. Their motives may be exceedingly praiseworthy, but unfortunately they have set about cleansing the Augean stable in the wrong way. A stream like the Irwell was one in which considerable latitude could have well been allowed, at the outset at any rate; but by following their mistaken policy they seem to be doing nothing but heap up a series of lawsuits at the ratepayers' expense. Let those who saw and smelt the Irwell in Jubilee year turn their attention to it now, and ask themselves if they can discern any improvement.

The first step towards promoting an amelioration would have been to have secured the adoption of any good precipitation process, and to have named a standard that could be obtained by such processes when fairly worked. If this had been coupled with an absolute prohibition of the entry of suspended matters into the river, it would for the present have been enough to ask for, and the various local authorities would have known how they stood, which is more than they do at the present moment. It is pretty well known that the sewage sludge is a difficult matter to deal with, and it is often found easier to precipitate by day and to do something else by night rather than let the sludge accumulate. It is very astonishing to find how much more sludge is now being obtained from certain works, owing to the frequent visits of the inspector.

But to return to the standard of sewage purification, it had been found by this city of Manchester such an intolerable burden that the Corporation actually contemplate spending a quarter of a million of money to avoid it. They cannot be blamed for this. As business men they see that it will be cheaper to incur this initial outlay than commence to experiment with land filtration on unsuitable land and restricted in area into the bargain. And here I may interpolate an objection to the proceedings of the Local Government Board in insisting upon the purchase of land for filtration purposes. Quite as good an effluent can be obtained with artificial filters as with the natural soil, and in many cases far better, but the Local Government Board do not seem to be aware of it. Between the Mersey and Irwell Joint Committee and the Local Government Board, those corporations who are anxious to improve the condition of things seem to be having a bad time of it.

Another subject I might dwell upon on an occasion like this is that of instruction in technical chemistry. We have now all of us become familiar with the jeremiads of many of our public men who never seem to miss the opportunity of declaring that the length and breadth of this land is a barren wilderness, and that if we want to find the veritable land of Goshen we must travel to Germany. While not wishing for one moment to disparage German methods and German industry, I say advisedly that we have still a few good men amongst us in the midst of our chemical industries

who are Britishers. That Germany has an excellent and cheap system of scientific education is known to everyone who has followed the subject, but I would join issue with those who think that anyone can be made a cooper to these spirits of industry whose originalities have revolutionised the world's methods, by a little scientific instruction—*"Made in Germany."*

We have now springing up in our midst—one in almost each of our large towns—palatial buildings called technical schools, which are supposed to be capable of exercising a huge influence upon our industrial operations in the near future, and they will no doubt be of use in winnowing the chaff from the wheat. A florist desirous of securing novelties in his business, sows the common seed broadcast, but he does not keep all his seedlings, and often enough uncommon means have to be pursued to secure the continuance of some original strain. Looked at in this light the technical school may be of use; it may select from among the class possessing but few opportunities, but from which all persons of note have ever sprung.

The technical school has in this quarter of a century become a necessity, mainly owing to the disfavour into which the system of apprenticeships has grown; the wages in many cases paid to apprentices or artied pupils being out of all rhyme and reason; and during the last years of an apprentice's "time," when he is doing the work of a skilled workman, to be receiving a paltry 12s. a week must be gall and wormwood to many an aspiring lad. Many firms will not take an apprentice; they have boys and youths working, but not under "indentures," and in many cases they are kept strictly to some monotonous routine.

Then again under the application of specialised machinery the sub-division of labour is so organised that in many shops the apprentice does not get an all-round grasp of a business, as he did in days gone by. It is here that the work of the technical school will come in, and such a school, if properly planned and equipped, will, in the future, be of immense value to our technical industries. Some few years ago I was shown round the new Polytechnicum at Zurich by Prof. Lunge, and marvelled at the completeness of the equipment. Here is an example that might well be followed by us: a good technical chemist at the head of affairs; he knows the details of which tuition and investigation are requisite, and the students' course is shaped accordingly. A man trained in such a laboratory will be of far more use to a manufacturer than if he studied in an ordinary laboratory under an non-technical professor.

It is the detail of industrial chemistry that requires study; the broad lines can be gathered from any technical treatise, but the detail and the investigation and cure of abnormal conditions can only be taught by one who has been through the school of adversity.

What we require in this country is a special chair of chemical engineering to prepare students for positions as works managers and superintendents of processes. It is strange how few chemists possess any knowledge of even elementary engineering, and fewer still any conception of practical mechanics; and yet an engineer will learn chemistry and apply his combined knowledge to the requirements of his profession. There is a field open here.

It was a bold experiment to place the funds necessary for technical instruction in the hands of local authorities with the full privilege of supplying whatever they deemed best. Let us hope the money will be better spent than it has been over the sewage problem, the annihilation of the smoke field, or even the prevention of the pollution of our rivers. If the precedent of these things be followed, we have as yet only reached the threshold.

I must say I have been astonished that the *cart-before-the-horse* principle seems to have been followed in many of these schools. The schools have been built and equipped with fixtures, and then, and only then, a director or professor has been deemed necessary. One would have thought the securing of a competent director or professor was the main point, and that he should be at hand during the building and the arranging and the fitting of the building which he is called upon to direct or to instruct in.

Fortunately Manchester—already possessing the nucleus of a technical school, with a director and instructors of no

mean ability, and assisted by such practical men as our late chairman, Mr. Levinstein—has not had the opportunity of making these mistakes; and I am of opinion that the Manchester Technical School, when it is finished, will be the exact thing required, which some of the other technical schools most assuredly are not. I have lately had an opportunity of forming some idea of what the Manchester school will be like when finished, and the only fault to be found is that in the very near future it will become too small for its work.

Has it ever occurred to any one of you that the number of highly educated technologists required yearly is comparatively but very few? But these establishments dotted over the country will produce many. What is then to become of them? This leads to the further question: For whom is technical education intended? I have a notion that it is for those who wish to become managers, overseers, or superintendents of processes in industrial establishments; but I am open to correction, as I know some people consider it to be provided for the rank and file. Of course it will be eligible for the rank and file, and so open out stepping stones for the eager and determined ones, but I fail to see how, in the majority of cases, the possession of a modicum of technical education will improve the work of the ordinary workman. There are many operations purely of a mechanical nature; the superintendent directs, the formula proceeds from the laboratory and director's office; the remainder could perhaps be executed in a better manner by a machine.

Do not think I am disparaging the spread of technical education—far from it, but I would warn you not to expect too much, in the near future at any rate; and in passing may just point out that I think the older teaching universities have been very remiss in days gone by in not supplying a curriculum rendered necessary by the progress of the age, and it is not at all to their credit that the technical education of the country should have been left to municipal corporations to supply.

In the earlier part of this address I pointed out to you the utterances of some of our public men, who have seemingly a very poor estimate of the power and industrial capacity of their own countrymen. Oddly enough they have a singular belief in those three magic words "*Made in Germany*," but as generally this expression is synonymous with cheapness on account of the low wages of the workers, I do not think we need trouble our heads about competition from this source. The day is coming, and very rapidly too, when Germany will have to pay her labourers much more reasonably, and then her costs of production will fall nearly into line with our own; but what I do fear is the coming competition with that remarkable race of English-speaking people, the Americans. America has made wonderful progress during the last quarter of a century, in mechanical devices mainly, but she is now turning her hand to chemicals, and a sad mess she has made already with English prices.

All new firms starting in this country for the supply of the American market should remember that America has a goodly supply of coal of all qualities, and that the price of labour is not inordinately high. The American chemical industries are manned by men who have a good scientific and industrial training, and to whom work is a pleasure. There are no works there left to an incompetent or underpaid all-round manager—a fact which we, sooner or later, will discover to our chagrin.

In my opinion, America cannot come to the front at once, owing to the strongly protective inclination of the majority of her legislators, and I do not see why our Cobden Club and other similar institutions should be so anxious to kick away the ladder just yet. For a market for our heavy chemicals we are largely dependent upon the United States, but so soon as the land of the Stars and Stripes becomes a Free Trade country we may begin to put our shutters up here. With Free Trade in the States we should no doubt have several years of unexampled prosperity, and then all would quickly vanish. America has all the raw material she requires; her coal, her oil, her natural gas, are all waiting for further development, which the natural industry of the inhabitants will not suffer to remain much

longer in repose. Of raw materials necessary for the chemical trade the States have abundance, while the adverse climatic conditions so often alluded to here, as being one great obstacle against the settling of the chemical trade in America, will yield to the ingenuity of the American people, who will quickly utilise the knowledge they have gained in their great technological institutions.

One lesson, I think, should have been well learned by this time, and that is, the folly of the different manufacturers of this country systematically underselling each other with the view of bringing the weaker to the wall. Even our greatest corporations will find out, if they have not done so already, that they are not improving their own positions by being ever on the consumer's doorstep with the promise to supply at lower prices than those offered by anyone else. It is like giving the consumer a blank cheque to fill in according to the dictates of his conscience, which, being rather elastic about the period of making his contracts, is not always to be depended upon. German competition becomes insignificant before this internecine warfare. There may be wisdom in it, but "the race is not to the swift nor the battle to the strong, but time and chance happeneth to them all."

On the motion of Mr. Harry Grimshaw, seconded by Dr. Grossman, a vote of thanks was accorded to the Chairman for his valuable address.

MR. THOS. FAIRLEY IN THE CHAIR.

THE DYEING PROPERTIES OF AROMADENDRIN AND OF THE TANNINS OF EUCALYPTUS KINOS.

BY HENRY G. SMITH, F.C.S.

In a paper read before the Royal Society of New South Wales on July last, I submitted the results of my investigations, so far as they had been completed, on the chemistry of *aromadendrin* ($C_{20}H_{26}O_{12} + 3H_2O$), a crystallisable body found existing in the "turbid group" of eucalyptus kinos. It was there pointed out that from the results of these inquiries, it was evident that *aromadendrin* had affinities, more or less marked, with catechin, obtained from cutch; but that in many respects it differed greatly from that body, and it was suggested that *aromadendrin* probably bore the same relation to the tannins of the eucalyptus of Australia as catechin bears to the catechin tannins. Thinking that perhaps the analogy might be further augmented by testing the dyeing properties of *aromadendrin*, I undertook a series of experiments in this direction, with the result that marked differences were found between it and catechin.

The results of this preliminary examination were left over until a future time for further investigation, only incidental mention being made in reference to it in the paper referred to above; attention was drawn to the fact, however, that when *aromadendrin* was heated to a little above its melting point (when decomposition takes place, although it melts without decomposition), a body was formed, almost insoluble

in cold water, soluble in hot water, exceedingly soluble in rectified spirit, and having great staining properties, dyeing cotton, &c. a fine yellow colour.

I named this substance *kino-yellow*, and considering its importance, left its investigation over until a future period. I was proceeding with the inquiry, when the June number of the Journal of the Society of Chemical Industry was received, which contains a paper by Messrs. J. J. Hummel and Reginald B. Brown on the "Dyeing Properties of Catechin and Catechu-Tannic Acid," a paper from which I have personally derived much information of the greatest use to me in carrying out this investigation. Thinking the results of my inquiries might be of interest to your Society, and have some value, I have submitted them with the hope that they may add somewhat to our knowledge of these bodies.

Before I make a short digression on the history of the eucalyptus kinos, I would refer to a portion of the paper by Messrs. Hummel and Brown, on page 426, where Mr. A. G. Perkin refers to the differences of the melting point of catechin as obtained by different observers, and remarks "that the higher melting products were difficult to understand." I had at first great difficulty in obtaining *aromadendrin* as a product of constant melting point, even when obtained from the same sample of kino, and by the same method; and it required to be obtained as white as possible by crystallisation from absolute alcohol before dissolving in hot water; if this be not done, the melting point will not be constant, even the slightest trace of impurity being sufficient to lower the melting point, and even repeated recrystallisation from boiling water does not successfully remove these impurities without much trouble. A portion of *aromadendrin* from the kino of *eucalyptus calophylla* was obtained, and its recrystallisation from absolute alcohol omitted, and although when crystallised from water it was quite white, yet it melted at $117^{\circ}C$. It was recrystallised no less than six times from water, and although the melting point was raised each time, it was not until the sixth time that a product having the correct melting point was obtained; whereas, by paying attention to the alcoholic crystallisation, at first, the white product, when afterwards obtained from water, usually melts near $216^{\circ}C$. the first time, and always after the second aqueous crystallisation, the melting point being more often above than below.

Eucalyptus Kinos.—The arboreal vegetation of Australia is largely composed of eucalyptus trees, belonging to the natural order *myrtaceae*, of which there are in the whole of Australia no less than 150 named species. These eucalyptus trees exude an astringent substance vernacularly known as "gum" (thus the term "gum-trees" as applied to the eucalyptus), but which is generally known as kino.

These kinos have been under investigation for some years at this museum, and a very fine and extensive collection has been got together. By this investigation we have been enabled to arrange them into some systematic order. We find that these eucalyptus kinos range themselves into three large groups or classes. First, those that contain about 35 per cent. of gum and are practically insoluble in alcohol, to this class belong all the exudations of the "ironbarks," and a few others. This group has been named the "gummy group," because of the gum present in the kino.

The second group has been named the "ruby group," because all these kinos are soluble in both water and alcohol, are ruby-coloured in thin pieces by transmitted light, and form ruby-coloured solutions. They consist almost entirely of a tannic acid and water, when freshly exuded, and contain neither gum nor *aromadendrin*. They embrace the exudations of the "stringybarks" and several others often with smooth barks. It is found however, that although the cortical classification of these kinos is useless, yet, the botanical sequence is complete so far as our knowledge goes.

The third group, known as the "turbid group," embraces all those kinos which are soluble in hot water but form turbid solutions on cooling. These belong to the "boxes," &c., and appear to contain all those kinos not included in the previous groups. It is this last group that is of interest to us in this investigation, as the bodies causing this turbidity have only been recently isolated and determined.

This turbidity is found to be caused by the presence of two bodies existing in these kinos, either singly or together, one named "eudesmin" ($C_{10}H_{16}O_2$), melting point $90^\circ C$, and aromadendrin. This latter body is the subject of this investigation, together with the kino from which it has been obtained, and also that of a specimen belonging to the "ruby group," while the affinities of "eudesmin" yet remain to be investigated. Very large quantities of these kinos are annually destroyed and lost. Very little has as yet been accomplished towards the commercial utilisation of very many natural vegetable products of this country. It is not my province in this paper to point out the errors that are passed on from one publication to another in reference to these eucalyptus exudates, but our knowledge is now such, that if properly collected and correctly classified, these kinos have great possibilities of commercial value and usefulness.

The Extraction of Aromadendrin.—The method whereby aromadendrin was obtained from these kinos is fully described in the papers submitted to the Royal Society of New South Wales, but it may be well perhaps to shortly recapitulate. The kinos were finely powdered, treated with a little water, and warmed; the particles thus disintegrate, and a pasty mass is formed; this is transferred to a separator, and, when cold, ether is added and continually agitated. No emulsion is formed, and the ether is readily removed; this treatment is continued with fresh ether, the several portions mixed, and the ether distilled off. The residue, which is usually reddish in colour, is then dissolved in the least possible quantity of boiling absolute alcohol, and allowed to stand some hours to crystallise; these crystals are then filtered off, drained on a porous slab, recrystallised again from absolute alcohol, drained, and dried; the crystals should be quite white; they are then crystallised twice from boiling water, when aromadendrin is usually found to be pure. Of course I refer to a kino in which "eudesmin" is absent.

The Dyeing Properties of Aromadendrin, &c.—The result of this investigation proves that pure aromadendrin in its normal condition has scarcely any dyeing properties when treated with copper sulphate and potassium bichromate, so that this body does not assist in dyeing when existing unaltered in the kino, thus differing from catechin. But when aromadendrin is heated to just above its melting point, and kino-yellow formed, it has marked dyeing properties when dissolved in boiling water and treated with $CuSO_4$ and $K_2Cr_2O_7$, or when dissolved in alcohol and the cloth dipped into the solution and dried before treatment with $CuSO_4$ and $K_2Cr_2O_7$. It is evident, therefore, that by turning aromadendrin into kino-yellow, it has dyeing properties somewhat analogous to catechin. Copper sulphate largely precipitates aromadendrin, but it does not precipitate the tannic acid, as exemplified with the kino of the "Blackbutt," *Eucalyptus pilularis*, which belongs to the "ruby group." I have not yet submitted the tannin of these kinos to comparative rigorous investigation, but there is little doubt from my researches that the tannin of all the eucalyptus kinos is identical. This being so, it follows that the copper salt being precipitated almost entirely by aromadendrin, but not by the tannin, only the tannin is of value when the copper salt is added directly to the solution of the kino; even if it is not so, it is proved by the experiments that aromadendrin has little dyeing properties with $CuSO_4$ and $K_2Cr_2O_7$ before heating. When aromadendrin is treated with ferric chloride solution, it is but little precipitated, and has very marked dyeing properties, but the tannin in the kino is wholly precipitated with $FeCl_3$, when in excess; so that in this experiment the dyeing properties of the kinos of the "turbid group" are almost entirely owing to the presence of aromadendrin in the kino. The kinos of the "ruby group" do not contain aromadendrin, and therefore have no dyeing properties with ferric chloride. $FeSO_4$ acts much in the same way and from the same reason. When the cloth is boiled in a solution of a ruby kino, and then in a solution of $K_2Cr_2O_7$, the tannin is oxidised as readily without the previous boiling in $CuSO_4$ as with it, the dye being just as dark; the only difference being that with the previous boiling with the copper salt, the dye has a slightly warmer tint. This

is so when $FeCl_3$ is added to the kino, but not in excess; so that it would be wasteful to add an iron salt, and the extra boiling in a copper salt assists but little in the process. It is thus seen:—

(a.) That neither $CuSO_4$ nor $K_2Cr_2O_7$ oxidises aromadendrin when in its normal condition.

(b.) That when changed to kino-yellow both $CuSO_4$ and $K_2Cr_2O_7$ are able to oxidise it, and also that the latter is able to do so without the previous boiling in the copper salt.

(c.) That $K_2Cr_2O_7$ oxidises the tannin of the kino without the previous boiling in the copper salt.

(d.) That the addition of $FeCl_3$ to a ruby kino has no effect, but that with a turbid kino, by acting with the aromadendrin, it assists by giving darker shades.

With $K_2Cr_2O_7$, the most successful experiment was when the cloth was boiled in the kino solution first, and then in the $K_2Cr_2O_7$ solution, because, although $K_2Cr_2O_7$ does not precipitate the tannin of the kino, yet it does not appear to act very energetically except when the chromate solution is in large excess; it readily oxidises the tannin upon the cotton when under the latter condition, but it acts very slowly when added to the kino solution directly. If it were possible to heat the kino to just above the melting point of aromadendrin without decomposing the tannin, the actual dyeing material would be greatly augmented in quantity; but it is not possible, as decomposition begins at a much lower temperature, and much of the tannin is destroyed at once. 36 specimens of dyed calico are submitted, illustrating the results obtained by the several treatments, and demonstrating the statements made above. The amount of material taken has been the same as given by Messrs. Hummel and Brown in their paper, *etc.*, 0.5 gram. of material made up to 50 c.c. in water, the size of the cloth being $3\frac{1}{2}$ in. by $2\frac{1}{2}$ in., so that comparative results may be obtained if required; but the time taken has varied, as stated in the following descriptions. In no case was the cloth left in the bath until cold, it being removed at the expiration of the time taken for boiling. The following numbers refer to the numbers above the specimens of dyed calico submitted with this paper, on the six cards.

Specimens Nos. 1 to 6.—Pure aromadendrin was dissolved in boiling water and the cloth No. 1 boiled in the solution for $\frac{1}{2}$ hour, then taken out, squeezed, and boiled in a solution of $CuSO_4$ for $\frac{1}{2}$ hour. This process was repeated; the cloth was then transferred to a solution of $K_2Cr_2O_7$ and boiled for ten minutes. The resulting colour, after the cloth had been washed in clean water and dried, was a very light drab, showing that this process had very little effect indeed on the cotton. With No. 2 the process was repeated on half the cloth; the resulting colour was very slightly darker than that of the first specimen. Nos. 5 and 6 are specimens of another kind of cloth treated in the same way, but with this difference, that the cloth was boiled one hour in the copper solution; the resulting colour is but little different. With Nos. 3 and 4 a minute trace of kino-yellow was added to the bath, the treatment being the same as with Nos. 1 and 2; the result is seen in the slight darkening of the cloth. These experiments prove, as has been before stated, that aromadendrin has really no dyeing properties with the above treatment.

Specimens Nos. 7 to 12.—Pure aromadendrin was heated to just above the melting point until decomposition began, kino-yellow being formed; this was dissolved in alcohol. No. 7 was simply dipped in the alcoholic solution, squeezed, and dried; the result is a fine yellow colour. No. 8. The kino-yellow as above formed was dissolved in boiling water, and the specimen boiled in the solution; a yellow colour is the result. With No. 9 half the specimen No. 8 was boiled in the aqueous solution of kino-yellow, to which alum had been previously added; the alum does not precipitate the kino-yellow; a fine yellow colour is the result. No. 10 was a specimen the same as No. 7, and was boiled for $\frac{1}{2}$ hour in the same alum solution as No. 9; the resulting colour is a fine yellow, perhaps inclining slightly to orange. No. 11 was a sample of white cloth boiled in the alum solution of kino-yellow for $\frac{1}{2}$ hour; the resulting colour is not quite so pure as with either No. 9 or No. 10, having a slight tinge of brown. No. 12 was a specimen

the same as No. 7, but boiled $\frac{1}{2}$ hour in aqueous solution of kino-yellow to which SnCl_2 solution (dissolved in HCl) had been added; the result is a fine yellow, slightly darker than No. 10.

Specimens Nos. 13 to 18.—These specimens show that although pure aromadendrin does not dye the cloth, yet, when changed to kino-yellow, it has that property.

No. 13 was boiled in an aqueous solution of kino-yellow for $\frac{1}{2}$ hour, then in CuSO_4 for one hour, and then for 10 minutes in $\text{K}_2\text{Cr}_2\text{O}_7$. The resulting brown colour is warm, perhaps inclining to orange-brown. A portion of No. 13 was again treated by the same process, with the result that with No. 14 a darkening has taken place, a warm brown resulting. No. 15 was dipped in an alcoholic solution of kino-yellow, dried, and then boiled one hour in CuSO_4 and then in $\text{K}_2\text{Cr}_2\text{O}_7$; the result is a little lighter colour than No. 13. No. 16 is a portion of the previous specimen; it was boiled in an aqueous solution of kino-yellow before boiling in CuSO_4 for $\frac{1}{2}$ hour, and then in $\text{K}_2\text{Cr}_2\text{O}_7$; a decided darkening has taken place. Nos. 17 and 18 show that $\text{K}_2\text{Cr}_2\text{O}_7$ has the power to alter the kino-yellow to a brown dye. No. 17 was boiled in an aqueous solution of kino-yellow, and then transferred to $\text{K}_2\text{Cr}_2\text{O}_7$ directly and boiled; the result is a yellowish-brown. A portion of this specimen was again treated by the same process, when an orange-brown colour is obtained.

Specimens Nos. 19 to 24.—When pure aromadendrin is treated with $\text{K}_2\text{Cr}_2\text{O}_7$ no result is obtained. These specimens show the action of FeSO_4 and Fe_2Cl_6 upon unaltered aromadendrin. These salts do not precipitate aromadendrin to any extent, but have the power of acting upon it, the action of FeSO_4 forming much the same colour as when kino-yellow is treated with CuSO_4 , but the FeSO_4 acts more energetically at first. No. 19 was only boiled 10 minutes in the solution of aromadendrin, to which FeSO_4 had been added, and then boiled in $\text{K}_2\text{Cr}_2\text{O}_7$; the result is a light brown, differing but little in depth of shade from the kino-yellow specimens that had been boiled one hour in CuSO_4 . No. 20 was a portion of previous specimen again treated by the same process; the result is a warm brown of a clear colour. Nos. 21 and 22 are little different from the preceding two specimens, although boiled for $\frac{1}{2}$ hour in the FeSO_4 plus aromadendrin solution. Nos. 23 and 24 show the action of Fe_2Cl_6 when added to aromadendrin, boiling $\frac{1}{2}$ hour, and then in $\text{K}_2\text{Cr}_2\text{O}_7$. The resulting colours differ little from those obtained when FeSO_4 was used, being a little more dull. No. 24 was darkened by repeating the process.

Specimens Nos. 25 to 30.—We now consider the action of the kino from which aromadendrin was obtained. No. 25 was boiled in a solution of the kino for $\frac{1}{2}$ hour, then in CuSO_4 for $\frac{1}{2}$ hour, and repeated the process before boiling in the $\text{K}_2\text{Cr}_2\text{O}_7$; the resulting colour is a dark brown, which, by repeating the process with No. 26, becomes darker. When the CuSO_4 is added to the solution of the kino, and the cloth No. 27 boiled one hour, the resulting colour differs little from No. 25. By repeating the process with No. 28 the colour was but slightly darkened. With Nos. 29 and 30, Fe_2Cl_6 was added to a solution of the kino, and the cloth boiled for $\frac{1}{2}$ hour before treating with $\text{K}_2\text{Cr}_2\text{O}_7$; the colour is dark brown, slightly slaty in tint. By repeating the process with No. 30 the colour is darkened. Judging by the results obtained by aromadendrin with Fe_2Cl_6 , it must be considered that, although the tannin is precipitated by Fe_2Cl_6 , yet this must exercise some action in the bath, because the resulting colours are darker than the kino itself.

Specimens Nos. 31 to 36.—We now consider the action of a kino belonging to the "ruby group," and therefore containing no aromadendrin. The kino taken was that of the "Blackbutt," *Eucalyptus pilularis*. By treating Nos. 31 and 33 in the same way as Nos. 25 and 26 we obtain colours almost identical with that of the latter specimens. This was what we might expect, if the tannins are identical, because we have seen that this treatment with CuSO_4 and $\text{K}_2\text{Cr}_2\text{O}_7$ does not affect aromadendrin. Nos. 33 and 34 were treated in the same manner as Nos. 27 and 28, and the resulting colours are almost the same as those of the latter. No. 35 is a specimen boiled in a solution of this

ruby kino, to which a small quantity of Fe_2Cl_6 had been added, and then treated with $\text{K}_2\text{Cr}_2\text{O}_7$; the resulting colour is the same as obtained by boiling in the kino itself, and then in the $\text{K}_2\text{Cr}_2\text{O}_7$ directly, showing that the iron salt has little effect upon this experiment, except to destroy a portion of the tannin. No. 36 is an abnormal specimen; this portion of calico when boiled in CuSO_4 had the salt deposited upon the fibre, and when afterwards boiled with a solution of aromadendrin a yellowish-green colour was obtained. It did not matter which was used first, the resulting colour was the same. It was a portion of cloth that had been used, but I have not succeeded in obtaining this colour on any specimens of new cotton cloth that I have used. I have not attempted to trace the reason, but no doubt it was caused by some treatment the cotton had undergone. As it stands, it is more interesting, perhaps, than useful.

The specimens submitted have undergone no other process than washing in pure water after removing from the dye-bath.

I have much pleasure in submitting the above results to your Society, as the investigation is, I believe, entirely new, and in doing so I would like to mention that the Technological Museum of Sydney (which is a Government Institution) will be glad to furnish information respecting the products of Australia to correspondents who may be interested, and will also have much pleasure in disseminating knowledge respecting the same, as the object of the institution is not only the collection and exhibition of all substances used in the arts and manufactures, but the furthering of our knowledge respecting the indigenous products of the colony of New South Wales.

The paper was illustrated by specimens of aromadendrin, the kino from which it was obtained, a sample of a kino belonging to the ruby group, and 36 pieces of calico dyed with aromadendrin; and various kinos, alone and in conjunction with copper sulphate, potassium bichromate, ferrous sulphate, and ferric chloride.

DISCUSSION.

Mr. A. G. PERKIN had read the above paper on "The Dyeing Properties of Aromadendrin" and that dealing with the same substance in the Journal of the Royal Society of New South Wales, and congratulated Mr. Smith upon the interesting results he had obtained in this somewhat new direction. Recently, more attention had been paid to the nature of the colouring principles and allied substances contained in the natural dyestuffs, and this work was gradually tending towards the arrangement of these substances in distinct chemical groups. For some time past it seemed therefore reasonable to expect that substances analogous to catechin or kinoin should exist in nature, and the isolation of eyabomaculin from the *artocarpus integrifolia*, and the discovery of eudesmin and aromadendrin pointed to a partial fulfilment of this expectation. During the discussion on Messrs. Hummel and Brown's paper he had taken the opportunity of making some remarks upon catechin, which were intended merely as a preliminary notice for the purpose of reserving the investigation. The work was being continued, but it appeared better as yet to make no definite assertion upon the subject, until the results obtained were ripe for publication, which he trusted would be during the present session. Kinoin also had been prepared and examined to see if it possessed the property of combining with mineral acids, as is the case with quercetin, but with a negative result. He therefore looked forward with much interest to the further work of Mr. Smith upon his new substances, and it was highly probable that the independent result of both this gentleman and himself which would be obtained in the study of what appeared to be closely allied compounds, would be of service to each during the prosecution of further work. He was obliged for the suggestion as to the purification of catechin by crystallisation from alcohol; for, though he had already applied this as a test for the purity of one product, he had not as yet employed it with the cruder material. A point not mentioned by the author of the paper, though possibly known to him, was the fact that aromadendrin yields with aluminium-mordanted cotton a yellow shade, which appeared to be extremely suggestive.

Hon. Local Secretary:

H. Schweitzer, 139, Front Street, New York, U.S.A.

Meeting held on Friday, October 23rd, 1896.

OPENING ADDRESS BY THE CHAIRMAN,

DR. CHARLES F. CHANDLER.

I THINK it my first duty to congratulate the Section on the success which has attended these first years of its existence. I am informed by the Secretary that out of 420 United States members of the Society of Chemical Industry, 306 have already enrolled themselves as members of the New York Section, 10 of these having joined during the past year. I also find that we have had a considerable number of papers, many of which were extremely interesting, and contained valuable additions to chemical knowledge.

It is also very pleasant to have had the opportunity of entertaining so many distinguished foreign members of our Society during the past year.

In thinking over the subject of the future usefulness of this Section, I have very carefully studied the address of our late President, which I presume most of you have seen in the Journal. Mr. Tyrer drew attention to the part which the Society of Chemical Industry has indirectly been able to take in Britain with special reference to the interests of chemical manufactures; and he enlarged upon the further influence which the Society may exert for the benefit of chemical industries. He spoke particularly of what had been accomplished in trade matters in which chemistry was involved, where the Council and different committees of our Society in Britain had been in consultation with local authorities in regard to many subjects of a chemical character, such as river pollution; smoke abatement; sanitary nuisance abatements; British regulations for the safety of employes in factories in which chemical operations were conducted—regulations, for instance, for white lead factories, to protect the workmen from lead poison; bleaching-powder factories, to preclude them from the breathing of chlorine; protection to employes in match manufactories. They are subjects on which our Section might give valuable advice.

The British Sections have given considerable attention to the revision of the patent law, for the better protection of chemical inventors. The Council is now considering, in conjunction with the Chamber of Commerce, the laws regarding food and drug adulterations; and especially internal revenue regulations with regard to the use of alcohol in chemical manufacturing operations, and the denaturalisation of alcohol in different ways for different purposes.

The conditions and relations of such societies as ours to legislation are so different here, that I find it impossible to formulate any recommendations; and yet it occurs to me that it might be worth while for all the members to consider the directions in which our New York Section might be of use in this country in bringing about improvements and better regulations in some, at least, of the directions to which Mr. Tyrer alluded.

Another subject to which attention was called was the importance of establishing technical schools, and the influence which the Society of Chemical Industry might exert in advising, in the formation of such schools, so that they might be organised upon methods which would result in the advantageous expenditure of the means placed at the disposal of such movements.

There is quite a variety, as I presume you all know, of guilds in England—old guilds that have come down from a very early date. Many of these guilds have accumulated large amounts of property, which, by the increase in value, place them in a position to offer large support to technical education; and there have already been established in England quite a number of technical schools with the aid offered by these guilds or companies.

Little has yet been done in this country in the way of establishing technical schools. Perhaps on some other evening I may be able to present to the members of the Society some details with regard to some of the technical schools in England and on the Continent. I have visited quite a number of them, as, for example, the famous schools in Berlin; and this summer I visited quite a number of the textile schools—at Leeds, where there is a school for spinning and weaving; at Mulhouse, where there is the famous chemical school which is largely devoted to dyeing, under the direction of Prof. Noetting.

It is possible that our Section might accomplish something by interesting itself in this subject of establishing technical schools in this country.

Another topic to which the ex-President alluded is one which we might well consider. That is, the establishment of research laboratories. I spent a day with the son of Mr. Ludwig Mond in inspecting the famous Faraday-Davy research school, which Mr. Mond has established in London at an expense of a million dollars, under the control of the Royal Institution. Possibly some of our members may be able at some future time to act as liberally in the direction of establishing research schools. At all events, in order to get such schools established, the subject must be discussed and its importance impressed upon the public; and I think it might be well, perhaps, for our Society to consider some day the proposition of establishing research laboratories, and publish the facts in such a way that some wealthy person, who seeks to do something for the benefit of the community, might give that direction to his generosity.

With regard to the usefulness of our Section, we may say that it has already promoted friendly intercourse among the chemists of New York. It serves to bring us together, to make us acquainted, and it enables us to help each other; and in that sense, and for that reason, I think our Section has already been a great success, and I hope that it will continue to become more and more useful, not only to each of us individually, but to us collectively as a profession and to the community.

I see that Prof. Woodruff Wilson, of Princeton College, gave one of the addresses at Princeton University, and I found this little statement in his address:—

"It used to be taken for granted—did it not?—that colleges would be found always on the conservative side of politics (except on the question of free trade), but in this latter day a great deal has taken place which goes far towards discrediting the presumption. The college in our day lives very near indeed to the affairs of the world. It is a place of the latest experiments: its laboratories are brisk with the spirit of discovery; its lecture rooms resound with the discussion of new theories of life and novel programmes of reform. There is no radical like your learned radical, bred in the schools; and thoughts of revolution have in our time been harboured in universities as naturally as they were once nourished among the encyclopaedists. It is the scientific spirit of the age that has wrought the change. No man more heartily admires, more gladly welcomes, more approvingly reckons the gain and the enlightenment that have come to the world through the extraordinary advances in physical science which this age has witnessed. But I am a student of society and should deem myself unworthy of the comradeship of great men of science should I not speak the plain truth with regard to what I see happening under my own eyes. I have no laboratory but the world of books and men in

which I live; but I am much mistaken if the scientific spirit of the age is not working in us a certain great degeocracy, and breeding in us a spirit of experiment and a contempt for the past. It has made us credulous of quick improvement, hopeful of discovering panaceas, confident of success in every new thing.

THE DETERMINATION OF SULPHATE AND CARBONATE OF LIME IN WHITE PAINTS.

BY G. W. THOMPSON.

IN my paper on the analysis of white paints, read before this Section at its meeting, May 18, 1896, I overlooked a very peculiar reaction between carbonate of lime and sulphate of lead. It is well known that sulphate of lead when treated with the carbonates of the alkalis, as carbonate of ammonia, carbonate of soda, &c., is decomposed, with the formation of carbonate of lead and sulphate of the alkali; but as sulphate of lead is practically insoluble, and the same is the case with carbonate of lime, it was not supposed that on treatment with water any reaction between these two insoluble substances would take place, at least with any degree of rapidity or completeness. Our astonishment was great, therefore, on finding that sulphate of lead is completely decomposed by carbonate of lime in the presence of water, and that by complete washing all the sulphuric acid can be washed out as sulphate of lime, if the carbonate of lime is in slight excess. Sulphate of lime, therefore, cannot be determined in a paint containing sulphate of lead and carbonate of lime by washing with water. The problem we set ourselves to solve was how to determine carbonate of lime and sulphate of lime in the presence of lead compounds. This we finally succeeded in doing with perfect satisfaction, by dissolving out the carbonate of lime in the cold by a mixture of 95 per cent. of alcohol and nitric acid, 1.40 sp. gr., mixed in the proportion of nine to one. We treat 1 grm. of the finely powdered sample four times by decantation with this mixture, allowing to stand 20 minutes between each treatment, filtering, and washing the paper with the same mixture. We evaporate the filtrate to dryness to expel the alcohol, and, as oxalic acid appears to be formed by the oxidation of the alcohol, sulphuric acid is added in excess, with the addition of more nitric acid if necessary, and the heating continued until fumes of sulphuric acid appear. After cooling, take up with water, make alkaline with ammonia and acid with acetic acid, heat until complete solution is obtained, pass sulphuretted hydrogen boiling, to precipitate lead and zinc if present, filter, and determine lime in filtrate, after precipitation as oxalate. We determine the total lime in the usual manner, deducting from it the lime found as carbonate, that is, the lime soluble in the solution given, the remainder being the lime as sulphate.

Illustrating the reaction between sulphate of lead and carbonate of lime, Mr. F. P. Ingalls took three and three-hundredths (3.03) grms. of sulphate of lead and 1 grm. of carbonate of lime, both prepared by him and chemically pure, and placed them in a flask with 650 c.c. of water, which was calculated as being more than sufficient to dissolve all the sulphate of lime formed; the flask was corked, and agitated occasionally for four days. The solution was then filtered and the residue collected and weighed. It was found to weigh 2.815 grms. If all the lime and sulphuric acid had been converted to sulphate of lead and dissolved in the water, the loss in weight would have been 1.36 grms., the actual loss in weight being 1.215 grms. An analysis of the residue showed it to contain no lime soluble in the alcohol and nitric acid mixture. The lime and sulphuric acid found were equivalent to each other, so that we get the residue to contain—

	Per Cent.
Sulphate of lime, anhydrous	5.79
Lead, equivalent to lead carbonate	93.51
	<u>99.21</u>

This residue, in other words, contained no sulphate of lead, that substance having been completely converted to sulphate of lime and carbonate of lead. To make clear our

conclusion on this point we would say that in accordance with the method outlined above we found no lime as carbonate; all the lime present, therefore, is present as sulphate, and, as the sulphuric acid was just sufficient to satisfy this lime as sulphate, there was none left to be in combination with the lead as sulphate.

FORMALDEHYDE AS A REAGENT.

BY H. ENDEMANN, PH.D.

THAT formaldehyde and phenol unite is known, and no particular difficulty seems to attend this reaction, which results in the formation of bodies which may be described as diphenol-methane.

In the case of carbolic acid, the composition of the body is—

These bodies are colourless, but if they are treated with a dehydrating agent like chloride of zinc or concentrated sulphuric acid, coloured bodies are formed, which become colourless again on the addition of water. The colour produced depends upon the nature of the phenol. The evanescent nature of these colours makes it difficult or perhaps impossible to accurately determine the nature of this reaction, which takes place under dehydration; the fact, however, that colours are produced makes it probable that methane-hydrogen and phenol oxygen are involved in this reaction under a process of condensation similar to such as are recognised as being the cause of the colour of certain triphenyl-methane derivatives.

In order to produce the reaction I dissolve some phenol in commercial formaldehyde or formalin on the cover of a porcelain crucible. I then evaporate at low temperature, not quite to dryness, and add concentrated sulphuric acid. As far as examined the colour reactions with the various phenols are:—

	The Solid.	The Solution.
Phenol.....	Fuchsin coloured	Fuchsin-coloured.
Salicylic acid	Red	Fuchsin.
Eugenol	Brown, with shade of Bordeaux
Carvacrol	Orange to orange-red
Guaiacol	Violet, quickly brownish-violet
Resorcin.....	Scarlet-red	Orange.
Hydroquinone	Brown	Brown.
Thymol.....	Faintly fawn-coloured (due to impurity?)
α -Naphthol ..	Green	Brown.
β -Naphthol ..	Green, then black	Green.
Pyrogallol ...	Red
Haematein ..	Red, then brown
Tannin	No reaction

This reaction is not confined to formaldehyde, but is likewise produced by other aldehydes. The colours, however, differ; for instance, phenol and benzaldehyde give brown solid and brownish-yellow solution. While we may therefore use formaldehyde as reagent for phenols, we may use the phenols as a reagent for formaldehydes.

The journals brought us lately the news of a process of weighting silk by converting the sericin or silk gum into an insoluble body by means of formaldehyde. I have employed the above-mentioned reaction for the purpose of discovering this practice.

White silk, when treated with concentrated sulphuric acid in the cold, does not exhibit any striking reaction. The silk becomes at first yellow—so does the solution, then orange, and while the silk is dissolved and water is absorbed from the air, the solution assumes a faint violet tint.

If the silk has been treated with formaldehyde to set the sericin, it becomes, with sulphuric acid, quickly a rich brown, and, after standing under a gradual absorption of water, olive-green to green. The fibre, although losing in cohesion, seems insoluble.

Silk treated with formaldehyde and then repeatedly and thoroughly washed with hot water does not respond to the reaction.

Wool reacts likewise becoming a rich brown. Also, in this case, we remove the possibility of obtaining the reaction. Whether the test will be applicable for the discovery of this adulteration will depend therefore upon the subsequent treatment of the silk.

DISCUSSION.

MR. WM. JAY SCHIEFFELIN remarked that the paper tended to illustrate the power of formaldehyde, and he had recently noticed that it had been suggested and tried as a preservative of milk. Although very poisonous, it was so very volatile that it was supposed the milk could be heated when it was needed, and all the preservative would be given off. It did not work that way. Formaldehyde stuck to the milk after it was put in, and so the experiment was considered a failure, although he understood some people still used it.

Obituary.

ALFRED H. MASON.

(FIRST CHAIRMAN OF THE NEW YORK SECTION.)

WE regret to announce the death in New York on the 2nd November, from pneumonia, of Mr. Alfred Henry Mason. Mr. Mason was so well known to members of the drug trade on both sides of the Atlantic that the announcement of his death will come as a sad shock to very many circles and individuals. He was not registered as a chemist in Great Britain, but was a pharmaceutical chemist of Quebec. Born at Newcastle, in Staffordshire, 54 years ago, he served his apprenticeship with Messrs. Marsen and Son, of Stafford. Subsequently he managed a business in Liverpool, and from thence he passed into the service of Messrs. Evans, Son, and Co. He filled various positions in that house for nearly 20 years, and in 1884 took up his residence in Montreal as the manager of the associated firm of Evans, Mason, and Co. (Limited). He next became associated with Messrs. Seabury and Johnson, of New York, and from 1889 to the end of 1892 he conducted the English business of that firm. In the beginning of 1893 he went to New York to undertake, in association with Mr. Seabury and Mr. J. M. Peters, the general management of the business there, including the manufacturing, which had grown with extraordinary rapidity. He had not since returned to this country. Wherever located—in Liverpool, Montreal, London, and New York—Mr. Mason associated himself with, and took an active part in, the work of the pharmaceutical associations of the city. He was at one time president of the Liverpool Chemists' Association, and he read many papers before that body. He was the first chairman of the New York Section of this Society, and at the time of his death was Secretary of the New York College of Pharmacy. He was to be found at all pharmaceutical meetings and discussions, and he made and kept hundreds of warm friends. The cordial esteem in which he was held was abundantly evidenced by the large gathering of wholesale and retail pharmacists who joined in giving him a dinner at the Café Royal to bid him farewell and God-speed when he last left this country for the United States. To all these, and to many others, the loss of this warm-hearted and versatile friend is a painful experience, associated with keen regret that a life which always seemed so full of activity should have been so suddenly brought to a close. Mr. Mason leaves a widow, a son, and two daughters.

I.—PLANT, APPARATUS, AND MACHINERY.

PATENTS.

Filtering Apparatus [Waste Oil, &c.], *Impts. in.* C. Whitfield, Kettering. Eng. Pat. 19,968, Oct. 23, 1895.

THIS apparatus consists of a settling tank and a filtering chamber. The dirty oil, &c., collected from the bearings and other parts of machinery, &c., is fed into the bottom part of the former, where part of the dirt is deposited. It then passes up through the settling tank and then through the filtering chamber. The clarified oil is drawn off from the bottom of the latter. The claim is for the "combination of a settling tank with a filtering chamber." Not only dirty oils, but other liquids may be filtered, it is stated, by the use of such apparatus.—R. B. P.

Filtering Material, *Impts. in the Composition and Manufacture of.* A. Smith, London. Eng. Pat. 22,127. Nov. 20, 1895.

THE claim is for the construction of filtering blocks or plates, the surfaces of which consist of a layer of a composition consisting of a mixture of kieselguhr, Roman or Portland cement, or both, and any suitable liquid, and the inner parts of any suitable material of a sufficiently coarse or porous nature.—A. S.

Fats, Oils, Resins, Sulphur, Colours, Tanning Materials, and the like: Impts. in or relating to the Extraction of, by Means of Volatile Solvents, and Apparatus therefor. J. Merz, Brünn, Austria. Eng. Pat. 16,766, July 28, 1896.

THE removal of the last traces of solvent from the extracted material is sought in this process, which is carried out in the apparatus illustrated in the accompanying diagram. The material to be extracted is placed in the vessel *b*, and the solvent allowed to flow in from the condenser *c*, through the tube *d*. The solvent then flows through the tube *e*, to the bottom of the surrounding vessel *f*, and is here again evaporated by means of the heating coil *g*. The vapours rise between the walls of the vessels *b* and *f*, heating the contents of *b*, and condense at the worm *h*. The condensed solvent flows back into *b*, extracts the material further, and

* Any of these specifications may be obtained by post by remitting 8d.—the price now fixed for all specifications, postage included—to Sir Henry Reader Lack, Comptroller of the Patent Office, Southampton Buildings, Chancery Lane, London, W.C.

flows again through *e* to *f*. This process is repeated until a sample drawn off through the cock *i* shows that the exhaustion of the material is complete. The condensing water is then shut off from the worm *h*, and steam of over

100° C. allowed to flow into the heating coil *k*. This has the effect of converting any liquid solvent remaining in the exhausted material into vapour, which vapour is driven over by steam. The steam and the vapour of the solvent are condensed in the condenser *c*, and the extract is finally drawn off through the cock *l*.—A. S.

II.—FUEL, GAS, AND LIGHT.

Acetylene, Explosive Properties of. Berthelot and Vieille. *Comptes rend.* 123, [14], 523–530.

ACETYLENE is an endothermic compound, the decomposition of which into its elements produces about as much heat as the combustion of an equal volume of hydrogen. Berthelot has shown that it can be caused to explode by the action of fulminate of mercury. On account of the increasing industrial importance of acetylene, the authors have investigated the conditions under which it explodes and the precautions which should be observed in dealing with it.

I. *Influence of Pressure.*—When the pressure is constant and equal to the ordinary atmospheric pressure, the decomposition of acetylene does not tend to extend beyond the point where it is first provoked (whether by a spark or by fulminate). Maquenne and Dixon have published interesting observations on this point (*Comptes rend.* 121, 1895). But under pressures of two atmospheres and beyond, acetylene exhibits the properties ordinarily observed in the case of explosive mixtures. Even if the decomposition be simply started by a platinum wire heated by an electric current, it is propagated throughout the whole mass of gas.

II. *Decomposition of Gaseous Acetylene.*—When the decomposition is started as above by a heated wire, the steel tube in which the gas is contained is found after the explosion to be filled with pulverulent carbon, and the gas in it is found to be pure hydrogen. The decomposition takes place strictly in accordance with the equation—

According to theory the temperature attained during the decomposition (at constant pressure) should be 2,750° C., and from this it follows that the final pressure should be 11 times the initial pressure. At comparatively low pressures the cooling effect of the walls of the tube is so great

as to considerably reduce the ratio of the final and initial pressures: e.g., when the initial pressure is 2.23 kilos. per sq. cm. the final pressure is only about 4.3 kilos. per sq. cm. But when the explosion starts at 21.13 kilos. per sq. cm. the ratio of the final to the initial pressure is as high as 10.13, which agrees sufficiently well with the calculation. The effect of the higher temperature and pressure is to increase the speed of decomposition as the initial pressure is increased. This increase is very rapid as we approach the pressure at which acetylene liquefies. In his researches on the formation of ethers, Berthelot has shown that this relation is general.

III. *Decomposition of Liquid Acetylene.*—Decomposition is propagated in liquid acetylene under pressure as easily as in the gas, even when it is only started by a hot wire, and especially when the volume is kept constant, as in a steel cylinder. But blows and shocks do not of themselves start explosions in such receivers, e.g., when they are allowed to fall on hard surfaces. Even when a receiver containing gaseous acetylene is smashed (e.g., a steel receiver holding a litre, crushed by a weight of 220 kilos. falling from a height of 6 m.) no explosion occurs. But when similar receivers containing liquid acetylene are smashed, the blow is generally followed by an explosion after a short interval. This, however, is not a direct effect, but is due to the ignition of the explosive mixture of acetylene and air (probably by sparks caused by the friction of pieces of broken steel). Similar results have been observed in the case of cylinders containing hydrogen under great pressure. Gaseous acetylene (pressure 10 atm.) contained in a wrought-iron bottle was not exploded under the impact of a ball which pierced one side and dented the other side. An iron bottle containing liquid acetylene was shattered to pieces when an explosion was started by fulminate of mercury.

IV. *Calorific Effects.*—Pictet has observed an explosion caused by the action of a small quantity of water on an excess of calcium carbide in a closed vessel. Local elevation of temperature may produce cumulative effects, first causing formation of condensed polymers of acetylene (benzene, styrene, hydride of naphthalene, &c.) with evolution of heat, and finally causing such an elevation of temperature as may determine an explosion. Too rapid condensation of the gas, or the sudden opening of a stop-cock, may also cause local heating, resulting in an explosion.

Finally, the authors are of opinion that all the above-mentioned risks can be guarded against by proper care in the preparation and manipulation of the gas, and that they do not constitute a serious bar to its use as an illuminating agent.—D. E. J.

Acetylene [Mixtures with Air]. Experiments on the Combustion of. H. Le Chatelier. *J. Pharm. Chim.* 1896, 4, 313.

MIXTURES of acetylene and air containing less than 7.7 per cent. of the combustible gas burn with a yellow flame, the brightness of which increases with the proportion of gas. The combustion is complete. From 7.7 to 17.3 per cent. the flame is blue; carbonic oxide and hydrogen are formed in addition to water and carbonic acid. At 17.3 per cent., part of the gas remains unburnt and carbon is separated, which with proportions above 25 per cent., forms a black opaque cloud.

The mixtures containing between 2.7 and 67 per cent. of acetylene are explosive; mixtures of coal-gas and air are not explosive until the former reaches 8.1 per cent. Acetylene is much more inflammable than other gases, even than hydrogen, the temperature of ignition being about 500°. The velocity of propagation in the most combustible mixtures, containing from 5 to 15 per cent., is between 4 and 8 m.; at 25 per cent. it falls to 0.1 m. per second, and at the superior limit, 65 per cent., is only 0.05 m. In mixtures corresponding to the highest velocity, containing 8–10 per cent., the flame will travel in tubes of 1 mm. but not of 0.5 mm. bore. The temperature calculated for the flame of acetylene burning in air is 2,400°, that of coal-gas being 1,900°. The separation of carbon from the acetylene flame may be overcome by burning the gas under considerable pressure from burners with a fine orifice, or, more conveniently, by mixing the gas with its own or twice its own

volume of air. This does not reduce the illuminating power; the use of 10–20 per cent. of oxygen would be preferable to that of air. To obtain these mixtures, the principle of the Bunsen burner might be used to obviate the storage of mixtures. By reason of its low temperature of ignition and low limit of inflammability, acetylene is said to be particularly suitable for small gas motors.—A. C. W.

Acetylene for Lighting Purposes, Report on the Preparation and Use of. M. Vieille. J. Pharm. Chim. 1896, 4, 315.

THE French commission appointed to consider this question is of opinion that installations for the production of more than 10 cb. m. per day should be placed under the same regulations as apply to the manufacture of coal-gas for private use. Special regulations for smaller installations have been made. From the experiments of Le Chatelier (see preceding abstract), mixtures containing 3 per cent. of acetylene must be regarded as readily explosive. The maximum pressure corresponding to complete combustion in the case of acetylene (the mixture contains 7.8 per cent.) is 8 kilos., in the case of coal-gas (15 per cent.) 6 kilos.

Experiments in which steel cylinders containing liquid acetylene or acetylene at 10 atm. pressure were subjected to violent blows or were crushed by a weight of 250 kilos. falling 6 m., or a wrought-iron bottle was pierced by a bullet, proved that under these conditions the gas does not detonate, though the rupture of the cylinders was soon followed by the explosion of the mixture of acetylene and air formed.

The regulations for small installations state that acetylene generators must be placed in the open air, and not in cellars or basements; reservoirs must also be placed in the open air and protected from the direct action of the sun; they must be officially tested at a pressure double that at which the gas is to be stored, if this is less than 10 kilos., and one and a half times as much if the pressure is to exceed 15 kilos. The cylinders should be of wrought iron or very mild steel, tested at 250 kilos. per sq. cm., the test being made every three years. The taps must be protected by covers of the same metal as the cylinders. The weight of the empty cylinder and its full charge must be marked on it; the charge should not exceed 1 kilo. for 3 litres capacity.

—A. C. W.

Coal, Calorific Value of; Calculation by Dulong's Method. Arth. Bull. Soc. Chim. 15, [18–19], 1112–1116.

IN a former communication (Bull. Soc. Chim. 13, 820) the author showed that the calorific values of many coals, calculated by Dulong's method, agreed closely with the results obtained by combustion in Mahler's bomb. In this paper are given tables of similar results in the case of coals which in the hands of former observers had shown discrepancies between the calculated and the observed values. In all these cases the agreement is very close, seldom amounting to 0.5 per cent. of the calorific value. Tables of data and details of methods are given in the paper.—J. T. D.

Incandescent Gas Lights [Influence of Composition of Mantles]. C. Killing. J. für Gas-beleuchtung, 39, [43], 697.

MANTLES made of thoria emit almost no light, whereas those consisting of 98–99 per cent. of thoria and 2–1 per cent. of ceria emit a brilliant light, owing to their power of converting a great part of the heat of the flame into light. To produce this effect the oxides need not be in "molecular mixture," such as is produced on mixing two solutions; if a previously burnt mantle of pure thoria is dipped into a weak ceria solution and again burnt, the same effect is obtained. A brilliant light is also given out by a mantle consisting of thoria, 99.75 per cent., and uranium oxide, 0.25 per cent. If, however, instead of ceria or uranium oxide a small quantity of yttria or ceria be added to a thoria mantle, its illuminating power is but little increased.

The author believes that only bodies possessing more than one degree of oxidation are capable of so exciting the illuminating power of a thoria mantle, and concludes that their action is catalytic; that by their mere presence in small quantity they act probably as bearers of oxygen.

Iridium, platinum, gold, and other metals can also act as oxygen-bearers, and when present in minute quantity in a thoria mantle, very considerably increase its illuminating power. All metallic oxides which exist in several degrees of oxidation improve the light-emissive power of a thoria mantle, but these oxides (e.g., oxides of chromium, iron, cobalt, manganese, molybdenum, &c.) are too quickly volatilised to be of practical value.

These conclusions are applicable not only to mantles having thoria as a basis, but also to those made from zirconia or from several oxides. It is therefore a real chemical action, catalytic in character, which causes the conversion of the heat rays into light rays.—H. B.

PATENTS.

[Hydrogen, Carburetted Hydrogen, &c.] An Improved Method or Process for use in obtaining Hydrogen Gas from Water, and means for obtaining by the aid of such Method or Process Carburetted Hydrogen and other Combinations of Hydrogen, and Apparatus for use in such Method or Process. J. Green, Wolverhampton. Eng. Pat. 13,510, July 13, 1895.

ACCORDING to claim, hydrogen gas is obtained from water by an improved process, "which consists in burning steam with hydrogen gas, or with carburetted hydrogen, or carbon monoxide within a suitable chamber."—R. S.

Fuel [Briquettes], Impts. in the Manufacture of. G. Hayeraft, Pontardulais, Glamorgan. Eng. Pat. 18,156, Sept. 28, 1895.

ARTIFICIAL and "practically smokeless" fuel is obtained by mixing small anthracite coal, waste charcoal, fine coke, coke breeze, and similar waste carbonaceous materials of a non-bituminous character with a proportion of small bituminous coal. The mixture is placed in a number of very narrow or shallow moulds, which are stacked in a series of ovens or chambers, into which heat may be introduced direct from a flue, or the connecting damper may be closed and the work performed by radiated heat alone. By this process an incipient coking of the bituminous coal takes place, which forms the cementing or cohesive medium in the fuel.—R. S.

Incandescence Bodies [Mantles] for Illuminating Purposes, Impts. in the Manufacture of. W. H. Wheatley, London. From C. Schmid, Brussels. Eng. Pat. 18,263, Sept. 30, 1895.

MANTLES are to be made in the usual way by impregnating a suitable fabric with aqueous solutions of the following salts, the fabric being afterwards burned off as usual:—

I. Lanthanum nitrate, 60.0 parts; strontium nitrate, 10.0; and silver nitrate, 0.25 parts.

II. Zirconium nitrate, 100.0 parts; strontium nitrate, 18.0; and silver nitrate, 0.5 parts.

III. Zirconium nitrate, 100.0 parts; calcium nitrate, 20.0; and uranium nitrate, 0.5 parts.—H. B.

New Burner, Blowpipe, or Bunsen Lamp, namely, an Appliance for Burning a Mixture of Air and Gas or Inflammable Vapours for the Production of Intense Incandescence of Mineral Substances employed for Incandescent Gas Lamps, known by the Name of "Auer Lamps," or "Von Welsbach," or other Analogous Lamps. [Air forced in.] J. de Brouwer, Bruges, Belgium. Eng. Pat. 20,697, Nov. 1, 1895.

IN this gas burner the air is admitted under pressure and draws the gas or inflammable vapours along with it, this being the reverse of burners at present in use. The apparatus consists of a cylindrical tube, swelled out or enlarged at its base, which is closed by a diaphragm at right-angles to the length of the tube. Through the centre

of the diaphragm, which is perforated with holes, passes the nozzle of the pipe admitting air under pressure. At right-angles to the air-pipe and to the cylindrical tube, the gas-pipe enters, its nozzle being in proximity to the nozzle of the air-pipe. The air forced in through the latter acts as in an injector, drawing the gas with it, gas and air supply being controlled by taps or regulators in the usual way. The Welsbach mantle or other incandescent body is fitted to the other end of the cylindrical tube by the ordinary arrangement.—H. B.

Incandescent Vapour Lamps, Impts. in. J. F. C. Jürgens, Altona, Germany, and A. B. Kisritz, Hamburg, Germany. Eng. Pat. 11,636, May 28, 1896.

An apparatus is proposed for burning petroleum and "liquid fuel rich in carbon" (as distinguished from spirit), so as to obtain a flame applicable to incandescent mantles of the ordinary type. Arranged in a circle are a number of upright tubes, each containing a wick, the lower end of which dips into the lamp reservoir. In the centre of the wick-tubes is a small petroleum suction-lamp, which, when lit, heats up the whole burner. The flame of this small lamp is prevented from communicating with the wicks, which surround it, by means of a circle of wire gauze, but the hot products of combustion vaporise the petroleum which has been sucked up by the wicks, so that a mixture results of petroleum vapour, the burnt gases from the small petroleum lamp, and the excess of air which the latter has drawn in. A further quantity of hot air is admitted through suitable openings in the lamp casing, and the gases are then intimately mixed by passing through a series of perforated discs, after which the mixture is burned beneath the mantle as usual. The air supply to the outside of the flame is previously heated by drawing it up through the double wall of the lamp. By means of a glass disc in the wall of the lamp, the heating flame can be watched, an outside metal knob serving to increase or lessen the latter. The gallery is arranged to slide up and down on the burner, so that the gas may be lit without the chimney having to be taken off.—H. B.

Incandescent Bodies or Mantles for Lighting Purposes. Impts. in the Manufacture of. [Using Crystalline Cerium Compounds, &c.] N. Caro, Rostrasse, Berlin, and W. Saulmann, Potsdamerstrasse, Berlin. Eng. Pat. 14,448, June 30, 1896.

THE light-emitting capacity of ceria-thoria mantles is not based on the existence of a compound of cerium-thorium oxide, but cerium in other than oxide form is capable of bringing the oxide of thorium, which in itself does not emit light, to incandescence. Compounds of cerium oxide with trivalent elements, such as arsenic, antimony, bismuth, boron, and vanadium, have the same effect as cerium oxide, and can be obtained, by solution, in a crystalline form upon the fabric itself. If, for example, a solution of cerium nitrate be mixed with a solution of arsenic acid, the mixture will remain clear; if it is boiled or steamed, the cerium arsenate will separate as a white crystalline precipitate. The patentee manufactures mantles by saturating the fabric with a solution of cerium nitrate and, say, arsenic acid. It is then dried, whereby arsenate of cerium separates in an insoluble form. The fabric is next saturated with thorium nitrate, dried, and burned off as usual. With boric acid, or acids of the other bodies above mentioned, the treatment is the same. Instead of the acids, other compounds of boron, &c. may be taken if these have the property of depositing from solutions in a crystalline form. Instead of cerium, other rare earths or their mixtures may be employed.—H. B.

Glow Lamps for Burning Vaporised Liquid Fuel, Impts. in. F. Schuchhardt, Berlin. Eng. Pat. 14,392, June 29, 1896.

In this device, the reservoir of liquid fuel (spirit, petroleum, benzene, &c.) is divided into two parts, the upper part communicating with the lower by means of a tube. From the lower container, rises a pipe (1), wherein the liquid is to be evaporated in order then to be carried off to the burner, which is at the upper end of the pipe. From the same container also rises, alongside pipe (1), a much

smaller upright pipe (2), serving to feed a heating flame. Pipe (2) is carried up to about the top of pipe (1), is then bent and carried down, and is bent up again with its mouth directed upwardly, so that when a flame burns at its mouth the flame plays upon both pipe (1) and pipe (2). When a flame has been applied to pipe (2), the vapours issuing from its mouth ignite, and thereafter evaporation goes on automatically, the "head" of liquid in the upper part of the reservoir maintaining the level of the liquid in (1) and (2) at about the level of the flame. The flame issuing from the mouth of (2) is sufficient, not only to produce enough gas for itself, but by heating (1) produces enough gas in it to supply the mantle burner.—H. B.

Incandescence Bodies [Mantles], Impts. relating to the Preparation of. W. P. Thompson, London. From R. J. Effe, London, and F. Meyer and Co., Berlin. Eng. Pat. 15,500, July 13, 1896.

CERTAIN oxides "are capable at high temperatures of taking up oxygen and yielding the same again." If small quantities (0.05 to 0.10 per cent.) of these "oxides of oxygen-conveying bodies" in a state of extremely fine subdivision be distributed throughout larger quantities of refractory (not oxygen-conveying) oxides, and the whole be exposed to the outer surface of a non-luminous flame, simultaneous reduction and oxidation takes place, and an intense light is emitted. The patentee makes, in the usual way, from a solution of the salts of the metals mentioned, an incandescence mantle consisting of oxide of calcium, about 27.5 per cent., oxide of zirconium, about 72.3 per cent., along with the "oxygen-conveyors"—oxide of vanadium, 0.10 per cent., oxide of ruthenium, 0.05 per cent., and oxide of rhodium, 0.05 per cent. He claims the use, in preparing incandescence bodies, of oxides of rhodium, ruthenium, and vanadium, singly or combined, in extremely fine division, and diffused throughout a compound of zirconia and calcium oxide.—H. B.

Electrical Glow Lamps, Incandescence Body for, and Process of Manufacture of the said Body. [Hollow Tubes.] J. F. Bachmann, A. Vogt, C. C. Weiner, Dr. J. Kirehner, and A. König, Vienna. Eng. Pat. 18,628, Aug. 22, 1896.

IN lieu of the ordinary filaments, the incandescence bodies for glow lamps are made of an intimate mixture of graphite or retort carbon and non-conducting refractory oxides (oxide of magnesium, calcium, or of chromium), or silicic acid or alumina, reduced to powder and intimately mixed together, first in the dry state, and then in a kneading machine with heat, and the addition of some binding agent, such as gum or tar. Whilst hot, the mass is pressed into the desired hollow form—say tubes of 3 mm. in diameter. These tubes are cut into suitable lengths, hardened in the air, and are then embedded in graphite in a cradle, which is heated to incandescence for 48 hours, either in a gas blow-pipe flame or in an electric furnace. Connection is made with the platinum or nickel, leading in wires, by means of middle contact pieces formed of small tubes of carbon, burnt after being moulded into shape, and then inserted into the unburnt incandescence body and raised to incandescence with it.—G. H. R.

Acetylene Gas, An Improved Method of and Apparatus for Generating and Regulating the Consumption of. J. C. Bayley, Bournemouth. Eng. Pat. 19,771, Oct. 21, 1895.

AN apparatus for the production and supply of acetylene gas, consisting of a gas generator, with removable perforated trays, in combination with a water tank.—A. S.

Acetylene Gas, Impts. in Apparatus for Generating. [Automatic Valve.] J. H. Exley, Huddersfield. Eng. Pat. 20,453, Oct. 30, 1895.

THE combination with an acetylene gas apparatus, of a valve located in the gas passage from the generator to the holder, and adapted to close automatically when a definite quantity of gas is stored in the holder, and remain closed until such quantity of gas is more or less consumed. (See Eng. Pat. 12,344, 1895; this Journal, 1896, 531.)—A. S.

Acetylene Gas, Impts. in Apparatus for Generating. [Connected Generators.] J. H. Exley, Huddersfield. Eng. Pat. 20,727, Nov. 2, 1895.

THE patentee claims the construction and arrangement of acetylene gas apparatus, whereby a second generator may be automatically brought into operation, and also the combination with acetylene gas apparatus of two check valves in the gas passages. (See Eng. Pat. 12,344, 1895; this Journal, 1896, 531.)—A. S.

Gas [Acetylene], Apparatus for Automatically Generating. G. Webb, Kennington, and W. Kelly, Finsbury Pavement, E.C. Eng. Pat. 5905, March 17, 1896.

THE apparatus, for generating acetylene from calcium carbide by the action of water, and for stopping the production thereof when the gas pressure increases, consists of two cylinders. The first or generating cylinder has a central tube open at both ends, an inner, removable receptacle for calcium carbide, and a close-fitting cover. It is connected to the second cylinder, or gas holder, by two short tubular connections having valves, one connection being above the carbide, the other near the bottom. The second cylinder is about twice the height of the first. It is divided into an upper chamber open to the air, and a lower closed one. The upper chamber contains water, which flows down a tube to the bottom of the lower compartment, and thence through the lower connection to the carbide. The gas generated passes through the upper connection to the lower compartment, and thence through a valved tube for use. If the valve is closed, the pressure of gas accumulates in the generator and in the top of the lower compartment, and drives the water from both to the upper compartment, thereby stopping the action of the generator.—R. S.

Acetylene, An Apparatus for Automatically and Safely Generating and Storing. [Ball- or Float-Valve.] E. Appleby, Leyton, and H. F. Harris, London Fields. Eng. Pat. 5976, March 17, 1896.

THE combination of a ball or float with a cock or valve placed in the pipe admitting gas from the gas generator to the gas holder, which ball at the proper time cut off the supply of gas from the generator into the holder.—A. S.

Acetylene Gas, Impts. in [Automatic] Apparatus for Producing. F. P. J. Ackermann, Marseilles, France. Eng. Pat. 14,278, June 27, 1896.

THE apparatus is arranged so that the generation of the gas is regulated automatically according to the amount consumed. It comprises a gas holder B, a water cistern C connected with the gas holder by the tube E, and one or more gas generators A, each connected with the gas holder by two tubes *a*, *c*, arranged at different levels. The water

is supplied to the generator through the gas holder B and tube *c*, and the gas generated passes through the tube *a* to the gas holder. The supply of water is automatically cut

off when the gas is generated in sufficient quantity to force the water in the holder B below the level of the tube *c*. When two (or more) generators are employed, the connections are such that the second comes into use after the first has been exhausted. A generator divided into compartments arranged to act on the same principle is also described.—R. A.

Acetylene Gas, Apparatus for Production of. R. Haddon, Strand, W.C. From A. Boter, Barcelona, Spain. Eng. Pat. 16,345, July 23, 1896.

THE gas generator is provided internally with a water reservoir, and above this reservoir with a number of shelves, on each of which a parcel containing "a determined quantity" of calcium carbide is placed. Above these shelves is arranged a revolvable arm or lever, which is connected through pawl and ratchet mechanism to the bell of the gasometer, so that as the bell sinks, the arm is rotated, and pushes off one of the parcels of the carbide into the water. The parcels may be replaced by tipping boxes, &c., the fastenings of which are released by the rotating arm.—R. A.

Acetylene Gas, Impts. in the Production of, and in the Means or Apparatus employed therein. A. J. Boulton, 111, Hatton Garden, Middlesex, From F. Alexandre, Paris. Eng. Pat. 16,728, July 28, 1896.

THE gas is produced by the action of moisture or aqueous vapours on carbide of calcium without bringing the latter into direct contact with the liquid. The carbide is placed in a porous receiver, which is provided with a suitable tap and burner, and is surrounded by another receiver filled with sponge, &c. The water is fed to the outer receiver by means of a siphon, and the vapours given off from the liquid pass through the porous receiver and decompose the carbide. The gas is produced as long as consumption takes place and the saturation of the absorbent mass is sufficient, but the action ceases when the consumption of the gas ceases, in consequence of the pressure of accumulated gas effecting the expulsion of the liquid from the absorbent material.—R. A.

Acetylene Gas, Apparatus for Generating. W. C. Clarke, New York. Eng. Pat. 17,450, Aug. 7, 1896.

THE apparatus comprises a tubular generating chamber having removable end caps, a water vessel adapted to be inserted in the chamber above the charge of carbide, a valve in the water vessel, and a projection on one of the end caps operating to open the valve as the cap is secured in place. By this means the water is not brought into contact with the carbide until the chamber is closed, so that no gas can escape.—R. A.

Fluid Hydrocarbons [Spray-Jet], Apparatus for the Burning of, for Lighting and Heating Purposes; Impts. in and relating to. J. McL. McMurtrie, 21, Prince's Street, Pollokshields, Glasgow, and Luce, Ltd., 121, West George Street, Glasgow. Eng. Pat. 21,089, Nov. 7, 1895.

THESE improvements are applicable to the apparatus described in Eng. Pat. 16,701, Sept. 5, 1893 (this Journal, 1894, 937), granted to J. M. McMurtrie, wherein steam or the vapour of light hydrocarbon oil is projected through a central jet or nozzle, which is surrounded by an annular chamber containing fluid hydrocarbon. The latter is thus "atomised" and passes to the burner. The fluid hydrocarbon is raised to the annular chamber from the tank containing it by means of compressed air.

According to the present invention, instead of forcing the oil up to the burner from the tank by pressure of air, the injector action of the steam, air, or hydrocarbon vapour is utilised to draw up the oil. The oil-supply pipe from the tank is connected with a tube extending from and concentric with the central nozzle through which the steam or vapour issues, so that the rush of the latter produces a partial vacuum, and the oil so drawn up is converted into spray by means of the jet. Three simple forms of nozzle are described.—H. B.

Manufacture of Gases [Oxygen and Hydrogen, by Solar Heat], Impts. in the. W. Calver, Washington, U.S.A. Eng. Pat. 21,468, Nov. 12, 1895.

THE decomposition of water into hydrogen and oxygen by the action of concentrated solar rays in presence of finely divided iron is claimed, and apparatus for effecting this described.—R. B. P.

Artificial Fuel [Briquettes], A New Adhesive and Agglutinating Substance for Use in Making. A. Zendroni, St. George's Avenue, London. Eng. Pat. 2993, Feb. 10, 1896.

THE following materials are introduced into a rotating steam-jacketed cylinder kept at a temperature of about 200° C.:—500 kilos. of pitch, 50 kilos. of resin, 100 kilos. of naphthalene, 100 kilos. of calcium carbide, 50 kilos. of lime, and 800 kilos. of well-ground coal. The mixture is used as the agglutinating material in the manufacture of briquettes.—R. S.

Automatically Producing and Burning Vapour, Impts. in and relating to Apparatus for, from Oils and Hydrocarbons. R. A. Poitrimol, Paris. Eng. Pat. 9366, May 2, 1896.

REFERS to Eng. Pat. 6245 of 1895 (this Journal, 1896, 344). A heavy or light oil or hydrocarbon is caused to pass to a vaporiser, either by capillarity with the aid of wicks, or by causing the liquid to traverse a filter-box by the aid of pressure, or by the aid of an apparatus for regulating the feed proportionately to the quantity of gas consumed by the burner, and for resisting counter pressure. The vaporiser is heated at first by any suitable means, but after the process is once started, it is heated by the flame from the burner only. The vapour formed is conducted by one or more tubes through the tube leading to the burner, whereby it is superheated. It then escapes through a jet in the centre of the tube leading to the burner, and, passing to the latter, carries with it a sufficient quantity of air, with which it intimately mixes, to form carburetted air, before its arrival in the burner. For feeding with liquid a series of such burners, a flexible feeding tube is placed in the liquid reservoir, and the free end of it may be raised out of or lowered into the liquid at will, so as to stop or start the flow thereof to the burner. An inclined pipe upon which the several parts of the apparatus are branched, leads from the reservoir, and the branches are also connected to another lower and smaller reservoir by means of a second inclined pipe, with the object of emptying the pipes thereinto when the feed has been arrested, and of obviating leakage.—R. S.

Vaporising and Burning Liquid Fuel [Liquid Blow-Pipe Burners], Impts. in Means for. G. Shenton, London, and D. A. F. de Villepigue, Paris. Eng. Pat. 16,425, July 24, 1896.

A BLOW-PIPE burner is used, intended to transform into vapour and to burn in this state and at a high temperature, essences, mineral oils, and liquid hydrocarbons in general. This apparatus consists of a vaporising chamber or tube, preferably horizontal, which is heated to start the process, by a lamp beneath. It is connected at one end with an overhead liquid receiver by a tube of small diameter, helically wound for some distance. The liquid passes from this tube through narrow passages, which can be shut by an external screw, and enters the vaporising chamber. It escapes, as vapour, under pressure, from the other end of the chamber to a burner provided with tubular passages and a plug perforated along its axis and terminating in a capillary tube forming the actual jet. A tube of about the same diameter as the vaporisation chamber, is fixed on the end of the burner, and is furnished with openings for providing air for combustion, and at the end remote from the burner with a converging cone. The latter in use becomes red hot, and the heat is conducted back to the chamber, whereby the liquid is vaporised without applying external heat. The flame is extinguished by shutting off the supply of liquid.—R. S.

Illuminating Gas [Carburetted Water-Gas, &c.], Impts. in the Treatment of. J. N. Knapp, Omaha, Nebraska. Eng. Pat. 17,729, Aug. 11, 1896.

THIS invention relates to the removal or extraction of tar, condensable vapours, &c., from illuminating gases, such as, for example, carburetted water-gas. The gas is first cooled to about 125° F., to condense the tar, &c., and is then passed through a centrifugal wheel, which causes it to impinge on baffle plates arranged to separate the tar, &c. The centrifugal wheel may also act as an exhaustor to draw the gas from the generator.—R. A.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

Kerosene Shale of New South Wales. C. E. Bertrand. Comptes rend. 123, [16], 615—617.

AS a rule the Australian boghead deposits consist of the remains of a single alga, *Reinschia australis*, the sole exception being that of Doughboy Hollow, where *Pila australis* is also present, although only to the extent of some 9 per cent. At the period of deposition the algae developed rapidly and formed immense quantities of gelatinous material, which subsided, enveloping the thalla along with a number of eocoidal bodies, such as minute vegetable detritus, spores, and pollen. The satiny appearance of the shale is due to this gelatinous matter, which has become changed into a yellow transparent body of vitreous and lustrous fracture, contrasting with the dull coal from the underlying humic material. Beyond traces of borings through the substance of the gelatinous material of the thalla, no indications of bacterial agency have been detected.

The boghead at Hartley is less rich in gelatinous matter, 43—54 per cent. instead of 84 to 91 per cent., and this decreases in the upper layers to about 1·5 per cent., so that spores, pollen, humified detritus, and mineral matters preponderate, forming a sporopolleniferous shale instead of an algal coal. The *Reinschia* are present in smaller quantity and less mature condition, and in the casing a foot above the boghead the gelatinous matter is only one millionth part of the amount found in the boghead itself.

The spores and pollen were derived from a very few species of plants, but their deposition was continuous during the formation of the coal, and gave rise to yellow lamella in the mass; their proportion amounts, however, to only about $\frac{1}{2}$ per cent. of the mass in the upper layers of boghead. The vegetable matter already in a humified condition at the time the boghead was formed, constitutes, according to the degree of alteration sustained, soft charcoal, or (if less modified) has absorbed bitumen and formed a bright coal, both these conditions being encountered side by side.

The bituminous matter has undergone but little condensation. By infiltration, subsequent to the deposition of the gelatinous mass, it penetrated and filled all the interstices formed therein, and thus came into contact with substances it was able to impregnate and colour.

Considerable shrinkage of the thalla is observed in all the specimens from these shales, those found in the Hartley deposit being only between 1/24th and 1/12th of their original volume.—C. S.

Metallic Carbides, Study of [Formation of Hydrocarbons]. H. Moissan. Proc. Roy. Soc. 60, 156—160.

IN this paper an account is given of the metallic carbides obtained in the electric furnace devised by the author. At the high temperature obtained, the metals gold, bismuth, lead, and tin do not dissolve carbon; liquid copper takes up a very small proportion, though sufficient to change its properties, such as malleability; silver at its boiling point dissolves a small quantity of carbon, which separates on cooling in the form of graphite. This melt of silver thus obtained possesses the curious property of increasing instead of decreasing in volume in passing from the liquid into the solid state.

A large number of metals combine with carbon, under the conditions studied, to form definite crystalline compounds. Thus the alkaline and alkaline earth metals yield substances of general formula $C_2M'_2$ or C_2M' , decomposed on contact with cold water, quantitatively into the hydrate and acetylene. The aluminium compound, C_2Al_3 , which crystallises in hexagonal laminae, yields methane when decomposed with water; while those of the cerium group of metals of composition C_2M' yield a mixture of acetylene and methane; while those of manganese, CMn_3 , and uranium, C_3U_2 , give mixtures of methane, hydrogen, and ethylene.

The second class of carbides, such as those of molybdenum, tungsten, and chromium, which form opaque crystals with metallic lustre, are not decomposed by water at ordinary temperatures.

The author considers that the decomposition of these carbides, with formation of hydrocarbons, generally gaseous, but in some cases liquid or solid, may serve to explain the formation of petroleum and of asphalt, as also of various volcanic phenomena.—V. H. V.

Methylated Spirit.

See under Trade Rep., page 838.

PATENT.

Coal-Gas, Impts. in the Manufacture of. J. T. Thomas, Bisham, Berks, and A. V. Hunt, Upper Thames Street, London. Eng. Pat. 18,395, Oct. 2, 1895.

In order to utilise the tar produced in the distillation of the coal, that tar, collected in the usual way, is mixed with a suitable proportion of inert matter, such as fine house-ashes, flue ash, and dust from furnaces, &c., and the mixture is subjected to distillation in the retorts along with the usual coal from which the gas is produced.—R. A.

IV.—COLOURING MATTERS AND DYES.

The Action of Light upon Dyed Colours. Report of Committee, consisting of Prof. T. E. Thorpe (Chairman), Prof. J. J. Hummel (Secretary), Dr. W. H. Perkin, Prof. W. J. Russell, Captain Abney, Prof. W. Stroud, and Prof. R. Meldola. (Drawn up by the Secretary.) Read before the British Association (Section B), Liverpool Meeting, 1896. (See this Journal, 1894, 803—807.)

DURING the past year (1895—96) the work of this Committee has been continued, and a large number of wool and silk patterns, dyed with various natural and artificial blue and green colouring matters, have been examined with respect to their power of resisting the fading action of light.

The general method of preparing the dyed patterns, and the manner of exposing them under glass, with free access of air and moisture, were the same as already adopted in previous years.

The thanks of the Committee are again due to James A. Hirst, Esq., in whose grounds the patterns were exposed at Adel, near Leeds.

Each dyed pattern was divided into six pieces, one of which was protected from the action of light, while the others were exposed for different periods of time. These "periods of exposure" were made equivalent to those adopted in previous years by exposing, along with the patterns, special series of "standards," dyed with the same colouring matters as were then selected for this purpose. The standards were allowed to fade to the same extent as those which marked off the "fading period" in previous years, before being renewed or before removing a set of dyed patterns from the action of light. The patterns exposed during the past year are therefore comparable, in respect of the amount of fading action to which they have been submitted, with the dyes already reported upon.

The patterns were all put out for exposure on July 19, 1895, certain sets being subsequently removed on the following dates:—August 12, September 3, September 20, 1895; April 1, July 9, 1896. Of these five "periods of exposure" thus marked off, periods 1, 2, 3 were equivalent to each other in fading power, whereas periods 4 and 5 were each equivalent to four of the first period in this respect; hence five patterns of each colour have been

submitted respectively to an amount of fading equal to one, two, three, seven, and eleven times that of the first "fading period" selected—viz., July 19 to August 12, 1895.

The dyed and faded patterns have been entered in pattern-card books in such a manner that they can be readily compared with each other.

The following tables give the general result of the exposure experiments made during the year 1895—96, the colours being divided, according to their behaviour towards light, into the following five classes:—Very fugitive, fugitive, moderately fast, fast, very fast.

The initial numbers refer to the order of the patterns in the pattern books. The S and J. numbers refer to Schultz and Julius's "Tabellarische Uebersicht der künstlichen organischen Farbstoffen."

In the case of colouring matters requiring mordants, the particular mordant employed is indicated in brackets after the name of the dyestuff.

BLUE COLOURING MATTERS.

CLASS I.—VERY FUGITIVE COLOURS. (WOOL.)

Many of the colours of this class have faded so rapidly that at the end of the first "fading period" (July 19 to August 12, 1895) only a very faint colour remains, and at the end of the fifth period (one year) all traces of the original colour have disappeared, the woollen cloth being either white or of a yellowish or greyish appearance.

Triphenylmethane Colours.

Wool Book IX.

Basic Colours:—

10. Victoria Blue R. Constitution not published.
11. New Victoria Blue B. Constitution not published.
12. Victoria Blue B. Hydrochloride of phenyl-tetramethyl-triamido-diphenyl- α -naphthyl-carbinol. S. and J. 274.
13. Night Blue. Hydrochloride of *p*-tolyl-tetra-ethyl-triamido-diphenyl- α -naphthyl-carbinol. S. and J. 275.
14. Victoria Blue 4R. Hydrochloride of phenyl-pentamethyl-triamido-diphenyl- α -naphthyl-carbinol. S. and J. 276.

Safranine Colours.

Basic Colours:—

24. Neutral Blue. Phenyl-dimethyl-*p*-amido-pheno-naphthazonium chloride. S. and J. 354.

Orazine Colours.

Acid Colours:—

9. Gallaniline Indigo PS. Sulphonated product of the action of aniline on galloeyanine-anhydride-anilide.
24. Fluorescent Blue. Ammonium salt of tetra-brom-resorufin.

Basic Colours:—

5. Capri Blue GON. Dimethyl-tolyl-ammonium-dimethyl-amido-phenoazoxazine chloride.
7. Cresyl Blue 2BS. Dimethyl-tolyl-ammonium-amido-phenoazoxazine chloride.
19. Nile Blue. Dimethyl-phenyl-ammonium- α -amido-naphthoxazine chloride. S. and J. 344.
20. New Methylene Blue GG. Dimethyl-phenyl-ammonium-dimethyl-amido-naphthoxazine chloride.

Thiazine Colours.

Basic Colours:—

3. Thionine Blue GO. Zinc double chloride of diethyl-dimethyl-thionine.
4. Methylene Blue B. Zinc double chloride of tetramethyl-thionine.
8. Gentianine. Hydrochloride of dimethyl thionine.
9. New Methylene Blue N. Hydrochloride of diethyl-tolyl-thionine.
- , Toluidine Blue. Zinc double chloride of dimethyl-tolyl-thionine. S. and J. 351.

Azo Colours.

Wool Book X.

Direct Cotton Colours:—

1. Diamine Sky Blue. From diphenitidine and amido-naphthol-disulphonic acid II.
2. Chicago Blue 6B. Constitution not published.
3. Brilliant Benzo Blue 6B. Constitution not published.
8. Diamine Blue 6G. Constitution not published.

NOTES.—Certain colours in this class—*e.g.*, Gentianine, &c.—fade during the first period to a grey colour possessing a moderate degree of fastness. Neutral Blue is characterised by fading to a dull reddish colour. Gallaniline Indigo PS and Diamine Blue 6G, when completely faded, leave the wool of a pronounced yellow tint.

CLASS II.—FUGITIVE COLOURS. (WOOL.)

The colours of this class show very marked fading at the end of the second "fading period" (August 12 to September 3, 1895), and after a year's exposure they have entirely faded, or only a tint remains.

Triphenylmethane Colours.

Wool Book IX.

Basic Colours:—

1. Turquoise Blue. Constitution not published.
2. Turquoise Blue 2B. Constitution not published.
6. Glacier Blue. Zinc double chloride of dicblor-dimethyl-diamido-ditolyl-phenyl-carbinol.

Acid Colours:—

5. Cyanol extra. Sodium salt of *m*-oxy-diethyl-diamido-phenyl-ditolyl-carbinol-disulphonic acid.

Thiazine Colours.

10. Thioearmine. Sodium salt of diethyl-dibenzylthionine-disulphonic acid.

*Orazine Colours.**Basic Colours:—*

27. Muscarin J. Dimethyl-phenyl-*p*-ammonium- β -oxynaphthoxazine. S. and J. 343.
28. Metamine Blue B. Dimethyl-phenyl-*p*-ammonium- β -naphthoxazine. S. and J. 342.
29. New Fast Blue H. Constitution not published.
30. New Fast Blue F. Constitution not published.

Acid Colour:—

27. Azine Blue. Constitution not published.

*Safranine and Induline Colours.**Basic Colours:—*

15. Basle Blue B. Dimethyl-amido-tolyl-amido-tolyl-pheno-naphthazonium chloride.
16. Diphen Blue R. An induline colour.
17. Indazine M. Tetra-methyl-diamido-diphenazine-phenyl-chloride. S. and J. 364.
26. Metaphenylene Blue B. Tetra-methyl-di-*o*-tolyl-diphenazonium chloride.

*Natural Colouring Matters.**Acid Colours:—*

1. Indigo Carmine. Sodium salt of indigotin-disulphonic acid.
2. Indigo Purple. Sodium salt of indigotin-mono-sulphonic acid.

Azo Colours.

Wool Book X.

Direct Cotton Colours:—

9. Benzo Cyanine 3B. Constitution not published.
11. Indoin Blue 2B. From Safranine and β -naphthol.
12. Metazurin B. Constitution not published.
14. Benzo Blue 3B. Constitution not published.
15. Benzo Red Blue G. Constitution not published.
16. Columbia Blue G. Constitution not published.
17. Chicago Blue R. Constitution not published.
18. Naphthazurin. Constitution not published.

23. Diamine Blue 2B. From benzidine and amido-naphthol-disulphonic acid II.
24. Diamine Blue 3B. From tolidine and amido-naphthol-disulphonic acid II.
25. Benzo Cyanine R. Constitution not published.
26. Indazurin. Constitution not published.
27. Direct Blue B. From dianisidine, dioxynaphthoic-sulphonic acid, and α -naphthol-*p*-sulphonic acid.
28. Heligoland Blue 3B. Constitution not published.
29. Benzo Azurine G. From dianisidine, and α -naphthol-mono-sulphonic acid NW. S. and J. 210.
30. Benzo Red Blue R. Constitution not published.
31. Columbia Blue R. Constitution not published.
32. Benzo Azurine 3G. From dianisidine, and α -naphthol-mono-sulphonic acid L. S. and J. 213.
33. Brilliant Metazurin OOO. Constitution not published.
34. Diamine Blue BX. From tolidine, α -naphthol-mono-sulphonic acid NW, and amido-naphthol-disulphonic acid II.
35. Diamine Blue B. From ethoxy-benzidine, β -naphthol- δ -disulphonic acid, and α -naphthol-mono-sulphonic acid NW. S. and J. 205.
36. Heligoland Blue R. Constitution not published.
37. Oxamine Blue 3R. From tolidine, β -amido- α -naphthol- β -sulphonic acid, and α -naphthol- α -sulphonic acid.
38. Diamine Blue 3R. From ethoxy-benzidine, and α -naphthol-mono-sulphonic acid NW. S. and J. 206.
39. Azo Blue. From tolidine, and α -naphthol-mono-sulphonic acid NW. S. and J. 187.
43. Azo Navy Blue. Constitution not published.
45. Direct Blue Black B. Constitution not published.

Acid Colours.

23. Azo Acid Blue B. Constitution not published.

*Natural Colouring Matters.**Mordant Colours:—*

Logwood (Al). Wood of *Hæmatoxylon campechi-anum*.

NOTES.—Azo Acid Blue acquires, on fading, a very red shade; Turquoise Blue 2B and Glacier Blue change to a green during the first period. Basle Blue B and Benzo Blue 3B lose their bloom of colour during the first "fading period," the remaining dark greyish colour being moderately fast. Direct cotton colours, 12, 17, 18, 23, 24, 25, change from blue to grey during the first "fading period," and Nos. 15, 16, and 26 to 39 all acquire a marked reddish tint. On this account these colours might almost equally well be placed among the "very fugitive colours."

CLASS III.—MODERATELY FAST COLOURS. (WOOL.)

The colours of this class show distinct fading at the end of the second period (August 12 to September 3, 1895), which becomes more pronounced at the end of the third period (September 3 to September 20, 1895). A pale tint remains at the end of the fourth period (September 20, 1895, to April 7, 1896), and at the end of a year's exposure the colour has entirely faded, or, at most, mere traces of colour remain.

Triphenylmethane Colours.

Wool Book X.

Mordant Colours:—

1. Chrome Blue (Cr). Oxy-carboxy-tetra-methyl-diamido-diphenyl-naphthyl-carbinol.

Wool Book IX.

Acid Colours:—

3. Patent Blue A. Calcium salt of *m*-oxy- (or *m*-amido)-tetra-alkyl-diamido-triphenyl-carbinol-sulphonic acid.
4. Patent Blue superfine. Ditto.
12. Alkali Blue. Sodium salt of mono- and di-phenyl-rozaniline-mono-sulphonic acid.

13. Alkali Blue 6B. Sodium salt of tri-phenyl-rosaniline-mono-sulphonic acid.
14. Hoechst New Blue. Calcium salts of tri-methyl-tri-phenyl-*p*-rosaniline, di- and tri-sulphonic acids.
15. Methyl Blue MB1. Sodium salt of tri-phenyl-*p*-rosaniline-tri-sulphonic acid.
16. Water Blue 6B extra. Sodium salt of tri-phenyl-rosaniline-tri-sulphonic acid.
17. Bavarian Blue DBF. Sodium salt of diphenylamine blue-tri-sulphonic acid. S. and J. 360.
18. Bavarian Blue DSF. Sodium salt of diphenylamine blue-di- and tri-sulphonic acid. S. and J. 299.
19. Alkali Blue D. Sodium salt of diphenylamine blue-mono-sulphonic acid. S. and J. 298.
20. Alkali Blue R. Sodium salt of mono-phenyl-rosaniline-mono-sulphonic acid.
22. Soluble Blue pure. Sodium salt of tri-phenyl-rosaniline-tri-sulphonic acid.

Orazine Colours.

Wool Book X.

Mordant Colour :—

5. Galloxyanine DII (Cr). Chloride of dimethyl-phenyl-ammonium - dioxy - phenoxazine - carboxylic acid. S. and J. 340.

Wool Book IX.

Acid Colour :—

35. Gallaniline Blue R. Constitution not published.

Induline Colours.

Wool Book IX.

Acid Colours :—

26. Milling Blue. Sodium salt of anilido-iso-naphthyl-rosinduline-mono-sulphonic acid.
28. Naphthyl Blue. Sodium salt of anilido-phenyl-naphthinduline-sulphonic acid.
29. Naphthazine Blue. Sodium salt of tetra-methyl-dianilido - dinaphthyl-diphenazonium - di - sulphonic acid.
30. Induline NN. Sodium salt of sulphonic acid of a Spirit Induline. S. and J. 366.
31. Indigen F liquid. Sodium salt of sulphonic acid of a Spirit Induline. S. and J. 365.
32. Induloe 3B. Sodium salt of sulphonic acid of a Spirit Induline. S. and J. 366.
37. Fast Blue B. Sodium salt of sulphonic acid of a Spirit Induline. S. and J. 365.

Basic Colours :—

22. Toluyene Blue B. Constitution not published.
23. Indamine Blue N. Hydrochloride of *p*-amido-phenyl-amido-derivatives of a Spirit Induline.
31. Paraphenylene Blue R. Hydrochloride of amido-phenyl-induline.
32. Indophenine extra. Constitution not published.
33. Indophenine B. Constitution not published.

Azo Colours.

Wool Book IX.

Acid Colours :—

38. Blue Black B. From β -naphthylamine-mono-sulphonic acid, azo- α -naphthylamine and β -naphthol-disulphonic acid R. S. and J. 134.
39. Indigo Blue powder. From toluene-azo-naphthylamine and β -naphthol-sodium-disulphonate.

Wool Book X.

Direct Cotton Colours :—

5. Brilliant Sulphon Azurine R. Constitution not published.
6. Sulphon Cyanine. Constitution not published.
7. Sulphon Azurine. From benzidine-sulpho-disulphonic acid, and phenyl- β -naphthylamine. S. and J. 182.
10. Sulphon Cyanine 3R. Constitution not published.
13. Brilliant Azurine 5G. From dianisidine and dioxy-naphthalene- α -mono-sulphonic acid. S. and J. 215.
19. Naphthyl Blue 2B. From *o*-amido-diphenylic acid, and benzoyl-amido-naphthol.

20. Benzo-Indigo Blue. From dianisidine, α -naphthylamine, and dioxy-naphthalene- α -mono-sulphonic acid (1:8).
21. Diamine Blue Black E. From ethoxy-benzidine, β -naphthol- δ -disulphonic acid, and γ -amido-naphthol sulphonic acid.
22. Blue JCR. Constitution not published.
40. Benzo Black Blue R. From tolidine-diazo- α -naphthylamine, and α -naphthol-mono-sulphonic acid NW. S. and J. 226.
41. Congo Fast Blue B. Constitution not published.
42. Benzo Black Blue G. From benzidine-disulphonic acid-diazo-naphthylamine, and α -naphthol-mono-sulphonic acid NW. S. and J. 225.
44. Congo Fast Blue R. Constitution not published.

Natural Colouring Matters.

Wool Book X.

Mordant Colour.—Logwood (Cr.) Wood of *Hematoxylon campechianum*.

NOTES.—The Patent Blues become darker during the first two fading periods. Brilliant Sulphon Azurine R acquires a decided reddish tint during the later stages of fading. The Sulphocyanines and Galloxyanine DII appear to be faster than the rest of the colours placed in this class, and do not change in hue during the fading process. The fastness of the Alkali Blues is probably greater than is usually supposed to be the case. The blue given by logwood with chromium is much faster than that obtained with aluminium mordant.

CLASS IV.—FAST COLOURS. (WOOL.)

The colours of this class show comparatively little fading during the first, second, and third periods. At the end of the fourth period a pale shade remains, which at the end of the year's exposure still leaves a pale tint.

Triphenylmethane Colours.

Wool Book X.

Mordant Colour :—

9. Gallein (Cr). Oxidation product of pyrogallol-phthalain. S. and J. 335.

Wool Book IX.

Basic Colour :—

25. Gentiana Blue 6B. Hydrochloride of tri-phenyl-rosaniline.

Orazine Colours.

Wool Book X.

Mordant Colour :—

7. Gallamine Blue (Cr). Product of action of nitroso-dimethyl-aniline-hydrochloride on gallamine acid. S. and J. 346.

Azo Colours.

Wool Book IX.

Acid Colour :—

36. Naphthol Blue Black. From *p*-nitraniline, aniline, and amido-naphthol-disulphonic acid II (1:8).

Induline Colours.

Acid Colour :—

33. Fast Blue 6B for wool. A sulphonated induline.

NOTE.—That Gentiana Blue 6B has proved to be fast is very remarkable, since the basic colours, and particularly those of the triphenylmethane group, are usually so fugitive. During the first fading period the bloom of the colour disappears, but the remaining colour fades very little, even throughout the period of a whole year.

CLASS V.—VERY FAST COLOURS. (WOOL.)

The colours of this class show a very gradual fading during the different periods, and even after a year's exposure a moderately good colour remains.

Oxazine Colours.

Wool Book X.

Mordant Colour :—

6. Cælestine Blue B (Cr). Constitution not published.

*Thiazine Colours.**Mordant Colours* :—

10. Brilliant Alizarin Blue R (Cr). Constitution not published. A derivative of oxy-naphtho-quinone-imide.
12. Brilliant Alizarin Blue G (Cr). Constitution not published.

*Oxyketone Colours.**Mordant Colours* :—

2. Alizarin Blue WX (Cr). Di-oxy-anthraquinone-quinoline. S. and J. 255.
3. Alizarin Blue S powder (Cr). Sodium bisulphite compound of Alizarin Blue. S. and J. 256.
4. Anthracene Blue WR (Cr). Hexa-oxy-anthraquinone.
8. Alizarin Cyanine R (Cr). Penta-oxy-anthraquinone. S. and J. 249.
11. Alizarin Cyanine G (Cr). Action of ammonia on intermediate product in making Alizarin Cyanine R. S. and J. 250.
13. Anthracene Blue WG (Cr). Constitution not published.
15. Alizarin Indigo Blue SW (Cr). Sodium bisulphite compound of tetra- and penta-oxy-anthraquinolin-quinone-sulphonic acid. S. and J. 257.
16. Alizarin Cyanine Black G (Cr). Constitution not published.

Natural Colouring Matters.

Wool Book X.

Direct Colour :—

1. Vat Indigo Blue.

*Additional Colouring Matters.**Acid Colour* :—

2. Prussian Blue.

NOTES.—The great fastness of the Brilliant Alizarin Blues is remarkable, since they belong to a group of colouring matters which has not hitherto furnished fast colours. The same remark applies to Cælestine Blue, although this colour is not so fast as the foregoing. The fastness of the various Alizarin Blues (oxyketone colours) is proverbial, and along with the colours just named they may well be regarded as worthy competitors of indigo for the production of fast blues. The chief difference of behaviour of Indigo Blue and some of the Alizarin Blues is that the latter tend to acquire a reddish tint, whereas the former does not.

The remarkable fastness of Prussian Blue on wool is such that the medium blue colour experimented upon has not perceptibly faded during a whole year's exposure, and it may be justly considered as the fastest blue on wool with which we are at present acquainted; unfortunately it is sensitive to the action of alkalis.

GREEN COLOURING MATTERS.

CLASS I.—VERY FUGITIVE COLOURS. (WOOL.)

Wool Book XI.

Basic Colours :—

1. Capri Green G. Constitution not published.
11. Solid Green 3B. Zinc double chloride of dichlor-tetra-methyl-diamido-triphenyl-carbinol. S. and J. 265.
13. Iodine Green. Zinc double chloride of chlor-methyl-hexa-methyl-rosaniline-hydrochloride. S. and J. 284.
15. Methylene Green. Nitro-tetra-methyl-thionine. S. and J. 349 (foot-note).
18. Aldehyde Green. Quinoline derivative of rosaniline. (?). S. and J. 377.

Natural Colouring Matters.

Wool Book XI.

Lo-kav (on cotton). Chinese dyestuff derived from *Rhamnus utilis*.

CLASS II.—FUGITIVE COLOURS. (WOOL.)

Triphenylmethane Colours.

Wool Book XI.

Acid Colours :—

1. Light Green SF (yellow shade). Sodium salt of diethyl-dibenzyl-diamido-triphenyl-carbinol-tri-sulphonic acid. S. and J. 268.
2. Helvetia Green. Sodium salt of tetra-methyl-diamido-triphenyl-carbinol-mono-sulphonic acid. S. and J. 266.
3. Light Green SF (blue shade). Sodium salt of dimethyl-dibenzyl-diamido-triphenyl-carbinol-tri-sulphonic acid. S. and J. 267.
4. Guinea Green BV. Sodium salt of nitro-diethyl-dibenzyl-diamido-triphenyl-carbinol-di-sulphonic acid. S. and J. 270.
5. Guinea Green B. Sodium salt of diethyl-dibenzyl-diamido-triphenyl-carbinol-di-sulphonic acid. S. and J. 269.
6. Fast Green extra. Sodium salt of tetra-methyl-dibenzyl-pseudo-rosaniline-di-sulphonic acid. S. and J. 286.

Basic Colours :—

3. Methyl Green. Zinc double chloride of chlor-methyl-hexa-methyl-p-rosaniline-hydrochloride. S. and J. 283.
4. China Green cryst. Tetra-methyl-diamido-triphenyl-carbinol oxalate. S. and J. 263.
5. Imperial Green cryst. Zinc double chloride of tetra-methyl-diamido-triphenyl-carbinol. S. and J. 263.
6. Solid Green GG. Tetra-methyl-diamido-triphenyl-carbinol sulphate. S. and J. 263.
9. Solid Green YVO cryst. Zinc double chloride of tetra-ethyl-diamido-triphenyl-carbinol. S. and J. 264.
10. Ethyl Green cryst. Tetra-ethyl-diamido-triphenyl-carbinol sulphate. S. and J. 264.

Mordant Colour :—

2. Chrome Green (Cr). Tetra-methyl-diamido-triphenyl-carbinol-carboxylic acid.

Safranine and Induline Colours.

Wool Book XI.

Basic Colour :—

17. Azine Green TO. Dimethyl-amido-phenyl-amido-phenyl-pbeno-naphthazonium chloride. S. and J. 363.

Azo Colours.

Wool Book XI.

Direct Cotton Colour :—

2. Columbia Green. Constitution not published.

CLASS III.—MODERATELY FAST COLOURS. (WOOL.)

Triphenylmethane Colours.

Wool Book IX.

Acid Colours :—

6. Alkali Green. Sodium salt of diphenyl-diamido-triphenyl-carbinol-mono-sulphonic acid. S. and J. 271.
7. Wool Green S. Sodium salt of tetra-methyl-diamido-β-oxy-naphthyl-carbinol-disulphonic acid.
8. Milling Green. Sodium salt of tetra-methyl-dibenzyl-pseudo-rosaniline-disulphonic acid.

Wool Book X.

*Azo Colours.**Direct Cotton Colour* :—

1. Diamine Green B. From benzidine, p-nitro-benzene-azo-amido-naphthol-disulphonic acid, and pbenol.

Mordant Colour :—

1. Azo Green (Cr). From m-amido-tetra-methyl-p-diamido-triphenyl-methane, and salicylic acid S. and J. 273.

CLASS IV.—FAST COLOURS. (WOOL.)

Wool Book X.

Direct Cotton Colour :—

3. Benzo Olive. Constitution not published.

Mordant Colour :—

4. Diamond Green (Cr). Constitution not published.

CLASS V.—VERY FAST COLOURS. (WOOL.)

Triphenylmethane Colours.

Wool Book X.

Mordant Colour :—

3. Cærulein (Cr). Product of the action of sulphuric acid on Gallen. S. and J. 336.

*Oryketone Colours.**Mordant Colour* :—

5. Alizarin Green SW. (Cr). Sodium bisulphite compounds of tri- and tetra-oxyanthraquinone-quinoline-sulphonic acids. S. and J. 258.

*Quinone-oxime Colours.**Mordant Colours* :—

6. Dark Green (Fe). Di-quinol-dioxime. S. and J. 232.
7. Gambine Y. (Fe). β -naphtho-quinone- α -oxime. S. and J. 231.
8. Gambine B (Fe). Constitution not published.
9. Naphthol Green B (Fe). Ferrous sodium salt of nitroso- β -naphthol- β -mono-sulphonic acid. S. and J. 236.
10. Dioxime (Fe). β -oxy-naphtho-quinone-oxime. S. and J. 235.
11. Gambine R (Fe). Naphtho-quinone-oxime. S. and J. 233.

NOTES.—The great fastness of the quinone-oxime colours when fixed with iron mordant is worthy of special notice. The fastness of Cærulein green as a Triphenylmethane Colour is also remarkable, but although Cærulein is usually classed as a Triphenylmethane Colour, its constitution when fully determined may cause it to be more properly placed in some other class.

SILK PATTERNS.

Most of the foregoing colours were also dyed on silk, and the patterns were exposed to light along with those on wool. The relative fastness of the various colours was, for the most part, the same as on wool, the differences observed being too unimportant to necessitate a special classification for silk.

The Chinese natural dyestuff Lo-kay fixed on silk with alum mordant is much faster than the same colour fixed on cotton from a soap bath. It was not found possible to apply it satisfactorily to wool.

Vat Indigo Blue is apparently less fast on silk than on wool, and on this fibre some of the Alizarin Blues, and notably the Brilliant Alizarin Blues, are much faster than Indigo Blue. As on wool, so on silk, Prussian Blue is faster to light than all other blues.

Indigo, Cultivation of, in Mexico. J. Soc. Arts, 1896, 44, 713.

THREE varieties of indigo are cultivated in Mexico, namely, *I. tinctoria*, *I. disperma*, and *I. anil*. Details are given as to methods of extraction and preparation for market, and it is finally stated that the actual cost of indigo-raising amounts, after the first year, to about 53 dols. per hectare.

Dye [Blue] for Wool and Silk. G. Ulrich. Färber Zeit. 7, [25], 396.

THIS new acid colouring matter, which is sold under the name of "Biebrich Acid Blue," is said to dye, at a temperature of 50°–70° C., in a mixed fabric of silk and wool, the silk only, leaving the wool woven with the former almost of its natural colour; whilst at boiling temperature both silk and wool may be dyed full "level" shades. This new dyestuff is said to go on very evenly, and is recommended for the dyeing of shot effects on goods composed of silk and wool.—I. S.

Phenosafranin and Rosinduline, Conversion of, into Parent Azonium Compounds. F. Kehrman. Ber. 29, 2316–2322.

THE author has succeeded in converting phenosafranin into phenylphenazonium by the following method. Aposafrafin chloride or sulphate is dissolved in a small quantity of water, and sufficient sulphuric acid is added to produce a pure green colour. Sodium nitrite solution is then quickly added until the whole is a dark orange-red, when it is treated with three times its volume of absolute alcohol. A violent evolution of nitrogen takes place, and after standing six hours the conversion into phenazonium sulphate is complete. The liquid is then treated with 10 grms. of ferric chloride for each 1 gm. of aposafrafin taken, and hydrochloric acid of 20 percent. strength, is added as long as a brownish-yellow precipitate of the ferric chloride double salt is formed. After filtering off and washing with cold glacial acetic acid, it can be recrystallised from boiling acetic acid, when it separates in reddish-brown shining prisms. For analysis, the salt is dissolved in lukewarm water, and the iron precipitated as hydroxide by the careful addition of ammonium carbonate. The azonium compound remains as a carbonate in solution, and can be obtained as hydrochloride by filtering into dilute hydrochloric acid. The addition of ammonia to the carbonate solution produces a deep magenta coloration and formation of aposafrafin, since, on adding acid, the solution does not turn yellow, as it would do were unchanged azonium base present. With soda lye, aposafrafinone is obtained, whilst dimethylamine produces violet dimethylaposafranin. Concentrated sulphuric acid dissolves the chloride with a red colour, almost of the same shade as that given by acetylaposafranin chloride, and from the great similarity in the physical properties of the phenazonium salts with those of acetylaposafranin, it follows that both substances have an analogous constitution, and that the salts of acetylaposafranin have an azonium formula. In a similar manner rosinduline chloride can be converted into phenyl-naphthophenazonium, which in solution is of the same shade and shows the same fluorescence as solutions of acetylrosinduline salts. The solutions also in concentrated sulphuric acid have the same shade, which also points to the fact that the salts of acetylrosinduline are azonium compounds. The phenyl-naphthophenazonium from rosinduline chloride is not identical, but is isomeric with that from β -naphthoquinone and phenyl-*o*-phenylene diamine, which can also be obtained by removing the amido group from the blue chloride isomeric with rosinduline chloride previously described (Annalen, 290, 275; this Journal, 1896, 536). The following formulae represent the constitutions of the two isomers :—

From Rosinduline.

From β -naphthoquinone.

The author considers that the evidence for the constitution of the safranines and rosindulines definitely points to the azonium formula. He reserves for a future paper a detailed criticism of the *p*-quinonoid theory, but makes reference to the principal points in dispute (O. Fischer, Ber. 29 1873; this Journal, 1896, 646). 1. It has been shown that aposafrafin and rosinduline can be diazotised in a strongly acid solution. 2. The basicity of the azonium compounds is a function of the substituents attached to the azonium nitrogen, and the more negative these are the easier does the transformation into the *p*-quinonoid and hence anhydride form take place. The fact that rosindone and aposafrafinone are weak bases does not preclude the possibility of their salts being azonium compounds. That acetyl aposafrafin carbonate is only partially hydrolysed

by water is easily intelligible, since acetylrosinduline, which is somewhat less basic, does not form a carbonate. 3. Fischer (*loc. cit.*) admits that the precipitation by carbonates or ammonia is no argument against the azonium theory, since he quotes instances of undoubted azonium compounds, which are precipitated by these reagents. 4. The azonium formula affords an explanation as to why the very faintly basic azines and erubodines, which do not yield carbonates are converted into stronger bases by the addition of the negative radicle phenyl, and then yield carbonates and salts with stronger acids, which, with few exceptions, are soluble in water without dissociation. 5. The formation of the acetyl derivatives by boiling phenosafranine, aposafranine and rosinduline chloride with acetic anhydride accords better with the azonium formula. 6. The azonium theory obtains especial support from the analogy existing between the non-amidated azonium salts and those safranine or rosinduline salts the amido groups of which are acetylated. 7. The quinonoid nature of the non-substituted azonium compounds, which from their formation and reactions must be *o*- and not *p*-quinonoid, is, like β -naphthoquinone, apparent from their behaviour to amines and alkalis, and thus the quinonoid character of the safranines, &c., cannot be used as an argument in favour of the *p*-quinone formula. 8. That the safranine and induline salts have the azonium formula, and that the rosindones and oxygen-free rosinduline bases are formed by a liberation of water accompanied by a molecular transformation affords the only explanation of existing facts. Even in cases where the liberation of water is impossible, instances of molecular transformation are known, and it has been found that nitro-isorosinduline gives two isomeric series of salts having the following formulae:—

Both these compounds can be converted into one another, give different sulphuric acid reactions, and correspond entirely to the two forms of *Orysonaphthophenazonium hydrochloride*—

The question as to the conjugation of the yellow diazo solution of phenosafranine and aposafranine (Nietzki, Ber. 29, 1445; this Journal, 1896, 537) must still remain an open one. At any rate, an alkaline β -naphthol solution is scarcely suitable for the purpose, since these diazo compounds, which at the same time have a quinonoid structure, are easily attacked by alkalis.—T. A. L.

PATENTS.

Triphenylmethane Series [Violet-Blue Dyestuffs], Manufacture of Derivatives of the. C. D. Abel, London. From "The Actien Gesellschaft für Anilin Fabrikation," Berlin, Germany. Eng. Pat. 23,051, Dec. 2, 1895.

This is an extension of Eng. Pat. 7550 of 1889 (this Journal, 1890, 386), and has reference to the preparation of triphenylmethane colouring matters from *o*-chlorodimethyl-*p*-amidobenzaldehyde, which is readily soluble in alcohol and ether, sparingly volatile with steam, and separates from an aqueous solution in small crystalline needles melting at 82° C. By combining one molecular proportion of this substance with two molecular proportions of an amine in

presence of or without a condensing agent, a leuco compound is formed, which on oxidation yields a basic colouring matter. For instance, 9 kilos. of *o*-chlorodimethyl-*p*-amidobenzaldehyde and 15 kilos. of dimethylaniline are dissolved in dilute sulphuric acid and heated for 24 hours. After neutralising with caustic soda, the excess of dimethylaniline is driven off with steam. The resulting leuco compound, after filtering off, is oxidised with lead dioxide, and yields the corresponding colouring matter, which dyes cotton mordanted with tannin a violet-blue shade, and gives a similar shade on wool from an acid or neutral bath. Acid colouring matters may be obtained in a similar way by substituting for the dimethylaniline above employed, either two molecular proportions of an amine sulphonic acid, or one molecular proportion of an amine and one molecular proportion of an amine sulphonic acid, the leuco compound produced in either case being subsequently oxidised. Thus by condensing in dilute sulphuric acid 9 kilos. of *o*-chlorodimethyl-*p*-amidobenzaldehyde with a mixture of 15 kilos. of ethyl-benzylaniline sulphonic acid and 6.1 kilos. of dimethylaniline, a leuco compound is obtained, which after oxidation yields a colouring matter dyeing wool bluish-violet shades from an acid bath.—T. A. L.

Sulphuretted Colouring Matters [Direct Dyes] Dyeing Non-Mordanted Fibres, Manufacture of. J. Murray, London. From "La Société Anonyme des Matières Colorantes et Produits Chimiques de St. Denis," Paris, France. Eng. Pat. 23,312, Dec. 5, 1895.

In Eng. Pats. 23,578 of 1893 and 3411 of 1895 (this Journal, 1894, 94, and 1896, 29) processes are described for obtaining colouring matters by the action of sulphur, with or without the presence of alkalis, on substituted aromatic amines or acetylated aromatic diamines. According to the present specification the *p*-diamines of the first-mentioned patent may be replaced by *m*-diamines, such as *m*-cresylene diamine or *m*-xylene diamine, or by substances which produce them on reduction with sodium sulphide, such as *p*-nitro-*o*-toluidine, *o*-nitro-*p*-toluidine, dinitrotoluene, or nitro-*m*-xylidine. A mixture of 100 kilos. of *m*-cresylene diamine, 200 kilos. of sulphur, and 400 kilos. of sodium sulphide is heated for five hours to 200°–250° C. The resulting black mass is soluble in water, alkalis, and alkaline sulphides with a brownish-red colour, but is insoluble in acids. It dyes unmordanted cotton yellowish-brown, fast to washing and the action of air and light. A colouring matter dyeing similar shades is also obtained by heating together for the same time to 225°–250° C., 100 kilos. of *m*-cresylene diamine and 250 kilos. of sulphur. This product is insoluble in water, but dissolves in sulphides.—T. A. L.

V.—TEXTILES: COTTON, WOOL, SILK, Etc.

Silk, Causes of Damage to. G. Giauoli. Chem. Zeit. 1896, 20, 821.

The diminution in strength of silk fabrics after dyeing is attributed mainly to the colours used and to faulty manufacture. Iron and stannous salts weaken the silk fibres, as does also an excessive quantity of mineral acid. Unnecessary stretching during the processes of dressing and weaving reduces the thickness of the threads. It is hoped that the use of injurious dyes will be abandoned. Further study of the process of dyeing will doubtless lead to the discovery of colours and methods of dressing by which the strength of the silk fabrics can be maintained unimpaired.—W. P. S.

Cotton Velvet, A New Method for the Production of Figured [Embossed]. M. Knoop. Bull. Soc. Ind. Mulhouse, 1896, 347–349.

WHEN caustic soda at 30°–40° B. is printed on a cotton fabric and the fabric dried without washing, the printed portions are considerably tendered. This fact can be made use of to produce embossed effects on pile fabrics and is particularly suitable for velveteens. Caustic soda of the above strength, thickened with baked starch or dextrin, is printed on the fabric, which is then dried, preferably on heated cylinders, and at once thoroughly brushed, when the

fibres weakened by the action of the caustic soda are broken off and removed; the fabric is finally washed and the pile re-dressed. The chief precaution to be observed is to brush out the disintegrated fibres immediately after drying, and since caustic soda is extremely hygroscopic, this cannot well be effected by hand in the case of large pieces, and brushing machinery should be employed. The author states that embossed patterns can be thus produced superior to any obtained by processes previously employed.

In a report which follows the description of the process, C. Sehoen confirms the author's statements, and declares that after thorough research he is unable to find any other substance which acts in this respect in a similar manner to caustic soda.—R. B. B.

PATENT.

Mercerising Cotton Fibres [Increasing Affinity for Dye-stuffs] without Shrinking. R. Thomas and E. Prevost, Crefeld, Germany. Eng. Pat. 18,040, Sept. 26, 1895.

THE object of this patent is to mercerise cotton in the yarn or woven piece without causing it to shrink. It is claimed that inasmuch as the mercerised cotton fibre has a much greater affinity for colouring matters than untreated cotton or silk, various colour effects may be produced on cloth consisting of cotton and silk, by subjecting the same, "whilst tightly stretched, to the action of suitable acids and bases," and washing the same, "whilst still under tension, until the strong internal tension present in the fibre has ceased." As an alkaline lye, the patentees employ "a concentrated solution of caustic potash or soda of, say, 15°–32° B., which has not any injurious action in a cold state upon the strength of the silk and cotton fibres, but which rather increases their strength." As acid, sulphuric acid of 49.5°–55.5° B. is recommended; "but when this is used, the process must be effected with more care, and the acid must be washed out thoroughly at once after a short period of action." The completion of the reaction is indicated by the parchment-like appearance of the fibre or fabric.—I. S.

VI.—DYEING, CALICO PRINTING, PAPER-STAINING, AND BLEACHING.

Cotton and Wool, Apparatus for Dyeing Loose.

Leipziger Färber Zeit. 45, [10], 415.

THE illustration shows an apparatus used in America for the dyeing of loose cotton and wool with substantive

colouring matters. It consists of a cylinder, radially divided into compartments and internally provided with bent hooks, which revolves in a semi-circular trough.—I. S.

Tannins, The Knowledge and Classification of. K. Krause. Chem. Zeit. 1896, 20, 794.

See under XXIII., page 831.

PATENTS.

Feathers, An Improved Method of Dyeing [Spraying]. H. N. Bour, Paris, France. Eng. Pat. 23,035, Dec. 2, 1895.

THE dye or other liquid to be applied to the feathers, is discharged in the form of a fine spray by means of an "atomiser." The feather may thus be dyed in one or different colours without taking the curl out of it, if it has already been curled in the ordinary way.—I. S.

Zinc Lactate as Mordant for Cotton. C. H. Boehringer Sohn, Nieder-Ingelheim-on-the-Rhine, Germany. Eng. Pat. 372, Jan. 6, 1896.

ZINC lactate is proposed in place of antimony compounds for mordanting cotton and other vegetable fibres. It is claimed that this salt is cheaper, and is fixed quantitatively by the tannin; hence a saving in cost is effected. The dye with basic colouring matters on zinc-tannin mordants is not so fast to washing as that on antimony; but this defect may be remedied by passing the zinc-mordanted goods through a second tannin bath.—I. S.

Printing Compositions for Printing [Bronze and Aluminium] upon Textile and other Materials, Impts. in. S. H. Sharp, Leeds. Eng. Pat. 16,274, July 22, 1896.

16.6 PARTS by weight of gum arabic, 50 parts of linseed oil, 16.7 parts of oil of resin, and 16.7 parts of dextrin are "boiled together to a syrup-like consistency." This mixture is called A.

Another mixture, called B, is made "by first boiling together, say for about three-quarters of an hour," 20 galls. of linseed oil and 40 lb. of red lead; then incorporating with this mixture 40 lb. of litharge and 80 galls. of turpentine, and boiling the whole "for, say, about an hour," and, when cold, filtering the mass through a woollen bag.

The mixtures A and B are incorporated together when cold in the proportion of about four parts by weight of mixture A to one part of mixture B, thereby forming a liquid, with which is incorporated "any desired aniline or other bronze powder," or aluminium powder, in the proportion of about three parts of the composition to one part of the powder.

Claims:—1. The herein-described manufacture of a bronze- or aluminium-coloured composition suitable for use in stencil printing machines for printing designs on textile and other fabrics, consisting of bronze or aluminium powder and a mixture of gum arabic, linseed oil, oil of resin, dextrin, red lead, litharge, and turpentine, substantially as described.

2. The manufacture, in the manner herein-before described, of the printing composition referred to in the preceding claim.—I. S.

Waterproof Fabrics, Impts. in. 1. Frankenburg, Salford. Eng. Pat. 650, Jan. 9, 1896.

THE waterproof surface of the material, either before or after vulcanisation, is printed with a composition of aluminium powder suspended in rubber solution, &c., in order to give it "the appearance of woven silk patterns, silk damasks, and all the varied styles of silk and half-silk fabrics." It is claimed that aluminium, as distinguished from other metallic dusts and bronzes, has no deleterious effect on the india-rubber.—F. H. L.

Waterproof Fabrics, Impts. in. 1. Frankenburg, Salford. Eng. Pat. 651, Jan. 9, 1896.

THIS is a modified form of the previous process. The aluminium, with or without other powdered material, is spread uniformly all over the fabric, which may afterwards, if desired, be printed upon in any suitable colours or patterns.—F. H. L.

Bleaching Kiers, Impts. in. M. Walton, Fratte di Salerno, Italy. Eng. Pat. 21,393, Nov. 12, 1895.

This invention relates to improvements in what are known as Mather kiers, and consists in means for making a more

perfect joint between the waggon in the kier and the pipe leading to the pump, the object being to improve the circulation of liquor, and to effect a saving in time and materials.

To the false bottom b^1 of the waggon is fixed a short flanged pipe c , the lower flange of which is faced to make a tight joint with the upper surface of a flanged collar d . The lower face of this collar is turned to fit into a cup or socket formed in the end of a short cylinder e , which is fitted and free to slide in a stuffing-box fitted into a casting, e^1 , secured to the kier. The collar d is connected to the cylinder e by a bolt d^1 , which retains it in position, but permits it sufficient freedom of movement in any direction for adjustment. The lower end of the bolt d^1 passes out of the cylinder e , through a stuffing-box f , and its lower end is connected to a weighted lever g , so that by moving the said lever, the sliding cylinder e and collar d can be raised and lowered as required. The lever g is worked by means of a hand-wheel and screwed spindle g^1 , or by any other suitable device. A pipe h^1 connects the cylinders e to a circulating pump h , which is connected by a pipe j to the upper part of the kier a . The pump h is also connected by a pipe to a superheater i , communication between the two being controlled by a valve. A valve j^1 on the pipe j opens or closes a communication between this pipe and a reservoir (not shown), and a valve j^2 opens or closes the connection between the pump and the pipe j with the top of the kier.

The operation is as follows:—Previous to running the waggons into the kier, the levers g are raised to lower the bolts d^1 , the sliding cylinders e , and collars d , so that

the flanged pipes c can come over the collars d . The waggons are then run into the kier up to the fixed stops (not shown), and the levers g are now lowered to raise the cylinder e and collars d against the pipes c . If desired, an india-rubber or other suitable flexible washer may be placed on each collar d to assist in forming a perfectly tight joint between the cylinders e and the waggons.

After the waggons have been filled with liquor, the door of the kier can be closed, and the valve m^1 and another valve (not shown) are closed, valves h^1 and another (not shown), opened, valve k^1 opened, and valve j^2 closed, and the pump set to work to draw the liquors from the bottoms of the waggons through the pipes c , sliding cylinders e , pipes h^1 , and pump, &c., into the bottom of the superheater i , which heats the liquor as it is forced through it up to the top, from which it flows through the pipe k and valve k^1 to the spreaders (not shown), by which it is distributed upon the goods in each waggon.—I. S.

Cups Dyeing, Scouring, Bleaching, &c.: Improved Machinery and Process for. W. Hepworth-Collins, Bradford. Eng. Pat. 3058, Feb. 11, 1896.

The apparatus consists of a metal cylinder a with a movable piston b , and piston-rod d , which passes through the bottom cover f of the cylinder. The piston consists

of four arms, a rim, and a boss to which the piston-rod is attached. (See Fig. 2.) The piston-plate *c*, or cop-carrier, is securely fixed by means of a water-tight joint to the

Fig. 1.

Fig. 2.

piston *b*, and is perforated to receive the hollow spindles of the cops. The piston charged with cops is pressed up and down by any mechanical means, whereby the liquor is forced through the cops, yarn, &c. in alternate directions.

VII.—ACIDS, ALKALIS, AND SALTS.

Solvay Process in the United States. Eng. and Mining J., Oct. 17, 1896, 367—368.

THE Solvay Process Company was established at Syracuse, N.Y., in 1884, for the manufacture of alkali by the Solvay ammonia process. At the present time the ammonia used in the process is obtained as a by-product in the manufacture of coke in ovens of the Semet-Solvay type.

The range of the Company's products, as at present made, is shown by the following list:—(1.) Soda ash, including 58 per cent. for easy dissolving; dense, 58 per cent. for melting purposes; 48 per cent. for general commercial use; special 48 per cent. for glass-makers; 36 per cent. for special chemical operation. (2.) Caustic soda, including high test 76 per cent. nearly chemically pure NaOH; 74 per cent., 70 per cent., and 60 per cent., the three customary commercial grades; special 70 per cent. and 60 per cent., made softer than the ordinary grades. (3.) Soda crystals, including monohydrate crystals containing 49.8 per cent. actual alkali; and snow-flake crystals, with 40.9 per cent. actual alkali. (4.) Bicarbonate of soda, including pure bicarbonate, 99 per cent. NaHCO₃ for baking soda, and anchor dust, an inferior grade for making carbonic acid. (5.) Crown filler, a pure hydrated sulphate of lime for surfacing papers. (6.) Chloride of calcium for use in refrigerating machines. (7.) Muriatic acid.

The growth and extent of the business is shown by the accompanying table, which gives the raw materials consumed and the products of the works from 1884 up to the close of 1895. The original capital of the company was 300,000 dols., and the output 30 tons of soda ash a day; the capital is now 4,000,000 dols., and the capacity of the works 600 tons a day. (For Table, see next page.)

Aluminium Acetate Solution. Vulpius. Chem. Zeit. 1896, 20, 795.

THE specific gravity of the basic aluminium acetate prepared according to the German Pharmacopoeia is 1.064—1.066, and not 1.044—1.046, as it is there given. A solution could not be prepared by any of the numerous suggested methods which did not give a precipitate on keeping. In determinations of aluminium in the acetate the method by evaporation of the liquid and ignition of the residue gives too high numbers.—A. C. W.

PATENTS.

Salt, An Improved Apparatus for the Manufacture of. A. R. Davis, Manchester. Eng. Pat. 19,692, Oct. 19, 1895.

The apparatus includes a furnace and combustion chamber, adapted to secure a smokeless flame; an evaporating chamber, in which a fixed depth of brine is maintained, the brine being sprayed by the rapid rotation of two shafts carrying fanners, which dip about half an inch into the brine; and a mechanical conveyor of the salt deposited in the trough-shaped bottom of the evaporating chamber. Pans are placed on the top of the furnace and evaporating chamber, fed with brine, to utilise waste heat. The products of combustion pass directly from the combustion chamber into the evaporating compartment, which opens into a chimney at the opposite end. The salt that deposits is withdrawn continuously, and is mechanically lifted by another conveyor on to a draining receptacle, whence the drainage returns to the evaporator. Other arrangements are shown in which the salt collects in a trough or troughs placed along the outside of the chamber, the conveyors being dispensed with, and the salt removed by hand. The process may be worked with gaseous fuel.—E. S.

Alkali Furnaces and the like, Impts. relating to Feed Hoppers for. F. H. Bowman, J. J. Howitt, J. Knowles, and T. A. Reid, Lostock Gralam, Chester. Eng. Pat. 21,267, Nov. 9, 1895.

The invention relates particularly to feeding bicarbonate into furnaces for the manufacture of sodium carbonate by the ammonia-soda process, and is intended to prevent loss of ammonia or influx of air during the charging. An iron box, circular in vertical section, is placed over the opening

to the furnace. The box has a hood or cover, with a sliding valve in the side for the introduction of the charge. A horizontal shaft, fitted to rotate, and carrying six radial blades which just clear touch with the periphery, passes axially through the box. As the bicarbonate is passed through the opening at the side and near the top, it falls upon the blade next below, and is carried by rotation downwards until it reaches and falls through the opening to the furnace, from what is then practically a closed chamber. The shaft may be rotated by hand, or by the weight of the material on the blades, or by power.—E. S.

Cyanides and Ferrocyanides, Impts. in the Manufacture of, from Sulphocyanides, and in the Recovery of By-Products. J. Raschen and J. Brock, Liverpool. Eng. Pat. 21,678, Nov. 14, 1895.

REFERENCE is made to Eng. Pats. 10,476 and 10,956, 1895 (this Journal, 1896, 543), on which the present invention is an improvement. Sodium or calcium sulphocyanide (preferably), with 4 to 5 parts of water, is allowed to fall gradually into a still containing water or mother-liquor from a previous operation, simultaneously with a separate stream of nitric acid, or of sodium nitrate solution mixed with sulphuric acid. The liquor in the still is kept near to its boiling point, and an agitator is used. An excess of acid is added. Air is excluded during the operation. The gases disengaged, consisting of hydrocyanic acid, nitric oxide, aqueous vapour, some higher nitrogen oxides, and carbonic acid gas, are passed through a scrubber containing water heated to about 80° C. to retain the nitrous fumes, and the dilute acid solution formed, may be used in the next operation. The unabsorbed gases are brought into contact with cold water, which absorbs most of the hydrocyanic acid, and are then passed through lime water, which takes up the

remainder, forming calcium cyanide, which may be decomposed to obtain an alkaline cyanide. The nitric oxide escaping from the lime scrubber, is mixed with steam and air to recover nitric acid. The solution of hydrocyanic acid obtained, is neutralised by an alkali to obtain sodium or potassium cyanide, the solution being preferably evaporated in a vacuum. A ferrocyanide may be obtained from the cyanide by known processes.—E. S.

Nitrogen Compounds [Ammonia as Final Product], Impts. in the Production of, and in Apparatus employed therein. (Under Intern. Convention.) T. L. Willson, New York, U.S.A. Eng. Pat. 21,755, Nov. 15, 1895.

A COMPOUND of a metal or metalloid is subjected to the intense heat of an electric furnace together with carbon in a current of nitrogen, to obtain a nitride, or in some cases a cyanide, from which ammonia may be produced. The apparatus consists of a pump by which air is forced into the bottom of a converter in which fuel is burned; a dust-separating chamber into which the nitrogen and carbon oxides from the converter are passed, and then conducted, either into the bottom or side of an electric furnace, or through the carbon electrode of the furnace, hollowed for the purpose. As an example of the process, a mixture of magnesia with granulated coke or coal-dust is heated in the manner described, to obtain magnesium nitride, which, when treated with water, yields ammonia. Nitrides of silicon, boron, aluminium, calcium, titanium, barium, &c. may be similarly produced. When a barium compound is used, however, "a large proportion of barium cyanide mixed with the carbide" occurs.—E. S.

Metallic Cyanides and other Nitrogen Compounds [Ammonia from Cyanides; the Cyanides from Carbides], Impts. in the Production of. (Under Intern. Convention.) T. L. Willson, New York, U.S.A. Eng. Pat. 21,997, Nov. 19, 1895.

NITROGEN is brought into contact with a carbide of a metal or metalloid, either simultaneously with the formation of the carbide from an oxide of the metal and carbon by electric smelting or otherwise; or when the carbide has been tapped off and is still in a molten state. Or a carbide, after cooling, may be fused and subjected to the action of nitrogen. The apparatus described, consisting of an electric furnace and accessories, is similar to that shown in Eng. Pat. 21,755, 1895 (see preceding abstract), except that provision is made for running off the molten carbide from the furnace into an adjacent receptacle into which a branch pipe conducts the mixture of nitrogen and carbon monoxide gases derived from the combustion of fuel. The pipe has also another continuation into the electric furnace, so that the conversion of the carbide into cyanide may, if desired, be effected before the carbide is run off. Examples are given of the formation of calcium and barium cyanides from oxygen compounds of those metals, fused with carbon and treated with nitrogen, and the process is stated to be applicable to the metals of the alkalis, as well as to silicon.

Cyanides obtained as described may be decomposed by superheated steam to obtain ammonia; or the cyanides of calcium and barium, for instance, may be decomposed by an alkali chloride to obtain an alkali cyanide.—E. S.

Alkaline Silicates, or Silicates of the Alkaline Earths, and of Chlorine or Hydrochloric Acid; Impts. in the Manufacture or Production of. D. A. Péniaikoff, Huy, Belgium. Eng. Pat. 22,037, Nov. 19, 1895.

A MIXTURE of silica with a sulphide and sulphate of an alkali or alkaline earth is heated to obtain the corresponding silicate and sulphurous acid. The proportions are taken according to the following equation:—

The sulphide may be replaced by an increased proportion of the sulphate with a suitable proportion of carbon, in which case carbonic acid is evolved with sulphurous acid. Or the sulphide may be replaced by pyrites in excess. The sulphurous acid obtained, may be utilised "for transforming alkaline chlorides, or chlorides of the alkaline

earths, into the corresponding sulphates and chlorine, or hydrochloric acid," by the processes described in Eng. Pat. 20,604, 1893 (this Journal, 1894, 947).—E. S.

Alkaline Aluminates, or Aluminates of the Alkaline Earths, and of Sulphurous Acid; Impts. in the Manufacture or Production of. D. A. Péniaikoff, Huy, Belgium. Eng. Pat. 22,038, Nov. 19, 1895.

ALUMINA and sodium sulphate are heated with one-fourth the quantity of carbon required for complete reduction. Under these conditions, instead of formation of a sulphide, sulphurous and carbonic acids are evolved, according to the equation—

Instead of alumina, red bauxite, consisting practically of alumina and ferric oxide, is preferably taken, and so much additional carbon as may be required for reduction of the ferric to ferrous oxide. The mixture is highly heated, with exclusion of air, and the effluent gases are conducted, either into a Hargreaves apparatus for recovery of alkaline sulphate, or into apparatus for obtaining sulphuric acid. The alkali aluminate produced may be extracted by washing.—E. S.

Aluminates and Sulphurous Acid, Impts. in the Manufacture or Production of. D. A. Péniaikoff, Huy, Belgium. Eng. Pat. 22,039, Nov. 19, 1895.

AN ALUMINOUS ore containing ferric oxide, such as red bauxite, is mixed with an alkali sulphate and either ferrous or ferric sulphide, and the mixture is calcined to obtain a mixture of alkali aluminate with ferrous oxide and sulphurous acid. The proportions used, according to the iron sulphide employed, are indicated by the following equations:—

The sulphurous acid disengaged is conveniently utilised as described in Eng. Pat. 20,604, 1893 (this Journal, 1894, 947), for transforming alkali chlorides or chlorides of the alkali earths into the corresponding sulphates and chlorine or hydrochloric acid. "The production of chlorine is rendered much easier by using, instead of atmospheric air, the well-known oxygen-yielding compounds."—E. S.

VIII.—GLASS, POTTERY, ENAMELS.

Composition of American Kaolins. C. F. Mabery and O. T. Klooz. J. Amer. Chem. Soc. 18, 10, 909.

THE authors give analyses of the kaolin used in the Royal Berlin factory at Charlottenburg, and point out they are characterised by a high percentage of silica and a low percentage of lime, iron, and alkalis. Analyses of a number of American kaolins are also given, from which the authors conclude that abundance of material exists in the United States for the manufacture of ware equal to the best European productions, but that the wide variation in the composition of American kaolins renders it necessary for the manufacturer to take careful note of analytical results before choosing his material.—V. C.

PATENT.

Enamelled Metallic Ware [Steel], Impts. in the Manufacture of. A. Niedringhaus, St. Louis, U.S. Eng. Pat. 16,107, July 21, 1896.

HERETOFORE iron has generally been used in preference to steel for the base of enamelled metallic ware, on account of the "pin-holes," "flicks," and "chips," which generally appear if steel be employed, although steel has been occasionally used with a double coating of enamel.

In the present invention, the "pin-holes" and other imperfections are got rid of by placing sulphur (with or without a chloride) in the annealing pot, either before or

after the shaping of the ware. The proportions required are about 2 lb. of sulphur to 100 lb. of steel, and the time of exposure to the sulphur vapour is from three to six hours.

—V. C.

IX.—BUILDING MATERIALS. CLAYS, MORTARS, AND CEMENTS.

Cement exposed to Low Temperature during Setting: Influence of Magnesia upon the Strength of. F. Haas and J. A. McGraw. *Thonind. Zeit.* 1896, 20, 535.

EXPERIMENTS were tried with five brands of natural cement, and with five of Portland cement, with the object of ascertaining the causes of the varying diminution in strength produced by freezing, even when the same proportions are used in mixing. The following conclusions may be drawn from the results:—1. The reduction in the strength is due to different causes in these two kinds of cement. 2. In Portland cement it is due to physical causes; and the effect of the magnesia present is insignificant as compared with these. 3. In natural cements, the percentage loss of strength varies directly with the increase in the proportion of magnesia, and physical differences play no appreciable part. 4. A Portland cement having a suitable chemical composition and a relatively low strength suffers a greater percentage loss through freezing than one of greater strength. Hence a heavy reduction in the strength of Portland cement points to want of care in its manufacture.—W. G. M.

Portland Cement: the Effect of Admixtures of Kentish Ragstone, &c. D. B. Butler. Abstract, separate copy. *Proc. Soc. of Engineers*, Nov. 2, 1896.

KENTISH rag is a sandy limestone of the lower greensand formation which is extensively quarried for building and road-making purposes. Some of the cement manufacturers uphold the view that a judicious mixture of this material improves the quality of Portland cement.

The author finds that, although it increases the cohesive strength of the sample, it invariably diminishes its adhesive power or cementing value when used in combination with sand or mortar or in concrete.—V. C.

Portland Cement, Methods of Testing at the Imperial Testing Station at Berlin. M. Gary. *Mitt. königl. tech. Versuchsanst. zu Berlin*, 1896, 155—191.

DETAILS of the mode, manipulation and methods employed for testing Portland cement at the testing station at Berlin are given.

Setting Time.—Seeing that the time of setting of cement is largely influenced by the percentage of water used to gauge it, it is important to determine the precise quantity strictly requisite for each sample. This end is attained by making a preliminary experiment on the quantity of water necessary to bring a weight of 300 grms. of cement into a syrupy consistency, so that it flows freely from a palette knife. Between 32 and 38 per cent. is usually requisite. Calling this quantity n , the percentage of water needed for gauging briquettes neat and with sand of quick-setting and slow-setting cements can be calculated according to the following empirical formulæ:—

Slow-setting cements:

$$\text{Neat tests, per cent. of water} \dots = \frac{n+1}{2}$$

$$1+3 \text{ cement, per cent. of water} \dots = \frac{n+3}{4}$$

Quick-setting cements:

$$\text{Neat tests, per cent. of water} \dots = \frac{n+2}{2}$$

$$1+3 \text{ cement, per cent. of water} \dots = \frac{n+6}{4}$$

These formulæ are found to apply with fair accuracy to normal Portland cements. They lead to a result of such a character that the neat tests are generally gauged with from

16 to 19 per cent. of water. In determining the setting time when the cement has been gauged with the quantity of water arrived at by the circuitous process described above, the Vicat apparatus is used.

Owing to the fact that a loose scum commonly accumulates on the surface of the test block, it is the practice at Berlin, when once initial setting has occurred, to reverse the block and take the true setting time on the bottom surface. It is also customary not only to take the temperature of the air at the time of setting, but also to observe its percentage of moisture by means of a hair hygrometer.

Fineness.—Great difficulty is experienced in the accurate determination of fineness, on account of the imperfection of most commercial sieves. Thus it is prescribed in the standard rules for cement testing, approved by the Association of German Cement Makers, that the 900-mesh sieve shall be made of wire, 0.111 mm. in diameter, and have a mesh opening of 0.222 mm.; the sieve actually in use at the testing station is made of wire 0.094 mm. in diameter, and is 0.230 mm. clear in the mesh.

Standard Sand.—One of the difficulties of obtaining reliable standard sand arises from the same cause as that mentioned under the previous head, *viz.*, the irregularity of the sieves commercially procurable. That this is sensible is apparent from the following figures:—

	No. of Meshes.	Width of Mesh.	Diameter of Wire.
1	120-mesh sieve.	mm.	mm.
2	120	0.60	0.30
2	121	0.654	0.255
Prescribed figures	120	0.589	0.32
1	60-mesh sieve.		
2	52.5	0.88	0.458
Prescribed figures	60	0.87	0.38

The considerable effect of the errors of construction may be realised when it is stated that with the sieves quoted above, No. 1 allowed 4.6 per cent. of standard sand to pass through it, and No. 2 as much as 35.4 per cent. The errors may be greatly enhanced by wear, the wires becoming more or less displaced. Similarly the irregular stretching of a piece of wire gauze on a round frame to form a sieve, will impair the accuracy of the width of the meshes, and square-framed sieves are generally preferable. Photographs of actual sieves are given on an enlarged scale demonstrating the exceeding irregularity of the best commercial sieves in width of mesh.—B. B.

Portland Cement, Manufacture of, in Belgium.

U.S. Consular Reports, Sept. 1896, 52, [192], 184—191.

NATURAL and artificial Portland cements are made in the district of Tournay, in Belgium. The calcareous stone of this region also yields common lime and hydraulic lime. The following products are of importance:—(1.) "Natural Portland cement." The stone used for this has the composition: silica, 15.75 per cent.; alumina, 3.95 per cent.; ferric oxide, 1 per cent.; lime, 43.1 per cent.; magnesia, 0.49 per cent.; sulphuric anhydride, 0.5 per cent.; carbon dioxide and water, 35.21 per cent. After burning, the clinker is cooled under sheds, ground, and the resulting cement stored in pits for two months. The annual output of this material is about 1,200,000 barrels of cement. (2.) Roman cement is also made in the same district from such stone as is inferior in quality to that yielding "natural Portland cement." The normal light yellow colour of the Roman cement is often masked by the addition of cinders, the mixture being fraudulently sold as Portland cement. (3.) Portland cement proper. The processes for making differ in no essential respect from those commonly adopted. "Some manufacturers rectify the composition of these cements after burning, by adding, as required, limestone, slag, &c. Cements are thus produced resembling in chemical constitution Portland cement, but which do not possess its properties on account of the constituent elements not having been forced into combination by calcination and semi-fusion of the mass. These cements are sold under the name of artificial Portland cements, though in reality

they are really mixed cements composed of limestone or slag possessing none of the qualities or properties belonging to real Portland cement."

Details are given of the methods of testing used by a Belgian cement company. Results are also quoted of certain commercial cements of Belgian origin, from which the following may be excerpted:—

(1.) "Natural Portland cement." One sample quoted had the composition: silica, 22.17 per cent.; alumina, 4.6 per cent.; ferric oxide, 1.23 per cent.; lime, 60.86 per cent.; magnesia, 0.73 per cent.; carbonic anhydride, 1.16 per cent.; water, 0.48 per cent. This material had a tensile strength at 7 days of 38 kilos. per sq. cm., and at 28 days of 44 kilos.; with sand (3:1) at 28 days the strength was 16.8 kilos. per sq. cm. Another sample of natural cement had the composition: insoluble siliceous matter, 4 per cent.; combined silica, 24 per cent.; alumina, 3 per cent.; ferric oxide, 2 per cent.; lime, 62 per cent.; magnesia, 0.6 per cent.; sulphuric anhydride, 1.2 per cent.; carbonic anhydride, 1.2 per cent. This gave a tensile strength at 7 days neat of 42.7 kilos., and at 27 days of 52.4 kilos., while sand tests (3:1) gave at 27 days 17.3 kilos. per sq. cm.

(2.) Portland cement proper. Typical figures are afforded by the following example:—The cement had the composition: insoluble siliceous matter, 1.6 per cent.; combined silica, 21.2 per cent.; alumina, 7.79 per cent.; ferric oxide, 1.27 per cent.; lime, 64.5 per cent.; magnesia, 0.59 per cent.; sulphuric anhydride, 0.6 per cent.; carbonic anhydride, 1.36 per cent. This cement had tensile strength at 7 days of 41 kilos. per sq. cm., and at 28 days of 68 kilos. when tested neat; sand tests (3:1) at 28 days gave a tensile strength of 39 kilos. per sq. cm.—B. B.

Normal Sands, Prussian, from Freudenwalde [for testing Cements and Mortars]; Comparative Investigations on. M. Gary. Mitt. königl. tech. Versuchsanst. zu Berlin, 14, 1896, [2], 103—112.

THE results of investigations as to the character of the material adopted in Prussia as normal sand, for use in cements, mortars, &c., are stated, with regard to physical condition and character and chemical composition. Also the resistance to strain and pressure of mortars made with this normal and sundry other sands with which it is compared, are given. The paper is illustrated with photographs and tables.

PATENTS.

Cement, An Improved [Admixture of Dextrin], and Means and Methods for Producing the same, and Architectural and other Works thereof. E. Robbins, Battersea. Eng. Pat. 18,331, Oct. 1, 1895.

THIS cement, which may be composed of lime, silica, magnesia, and zinc salts, with the addition of dextrin or other binding material, is said to possess adhesive, cementing, and strengthening properties, and to be very generally applicable to constructive and decorative work.—V. C.

Kilns, Impts. in Continuous-burning [Utilising Waste Heat], for Burning Bricks and other Clay Goods, and also for Limes and Cements. H. R. Vaughan, Belfast. Eng. Pat. 20,540, Oct. 31, 1895.

IN these kilns the flues are arranged so as to withdraw the waste heat from the goods in the burnt chambers and to convey it through the chambers which contain the "green" goods, which are thereby wholly or partially dried. This not only economises fuel, but improves the colour of the goods by drying them before they are brought in contact with injurious gases.—V. C.

X.—METALLURGY.

Metals, The Structure of: its Origin and Changes. F. Osmond and W. C. Roberts-Austen. Proc. Roy. Soc. 60, 148—152.

AS it is possible to distinguish in metals and alloys both the visible and molecular structure, it was thought of interest to ascertain to what extent the mechanical properties of a given sample of metal are due to each of these kinds of

structure and how far to their mutual relations. The samples of gold containing 0.2 per cent. of foreign elements which were used by Roberts-Austen in establishing the relation between tenacity and atomic volume were subjected to microscopical examination. The methods of preparing, polishing, and etching the micro-sections of these gold specimens, and photographs of the sections, are fully described. From the results, the authors conclude that there is no relation between the structure, the appearance of the fractures, the melting points of the alloyed elements, and the mechanical properties of the masses of the alloyed gold. They observe that the micro-section of the gold with potassium would indicate a highly favourable metal in respect to mechanical properties, viewed in the light of similar indications in steels, whereas it is itself the worst alloy of the series. On the other hand, the micro-section of the gold alloyed with zirconium would indicate great structural weakness, whilst, as a matter of fact, it might equally well represent alloys which vary in tenacity from less than half a ton to 7½ tons per sq. in., and which might be either incapable of extension, or be capable of elongation as much as 30 per cent.

The authors conclude the first part of the paper by saying that they do not contest in any way the importance of the part which may be played in the mechanical properties of the alloys by the residues which remain liquid after the main mass of the alloy has solidified, which residues constitute the *eutectic* alloy, and to which the name of "cements" has been given. However, in order that it may be possible for such cements to affect the mechanical properties of alloys, they must have a real existence, and nothing indicates that they do exist in 10 out of the 12 alloys examined in the present instance. It is possible, at the same time, that some new method of etching may reveal new facts on the point. Small secondary crystals at present show themselves, and might readily be taken for cements if they were found only in certain specimens, and in such proportions as could be accepted. But they occur everywhere, and in all cases with identical appearances, forms, and dimensions, and, moreover, are collected into crystallites which pervade the whole mass. These are, therefore due to the crystallisation of the gold itself, although the alloying substances sometimes join up the crystals in question. The dark lines of the joints traced as furrows by the etching are very rarely the empty tracks of cement which has been dissolved away by *aqua regia*, but are connected with the secondary crystallisation. It is believed that in 10 of these alloys the solidification of the mass has been directly accomplished at a single time, and that the foreign bodies have remained as solidified solutions in the same manner that they were fluid solutions when the alloys were liquid. The cement question in respect to explaining the mechanical properties of these alloys is hypothetical.

IN the second part of the paper it is pointed out that gold alloyed with bismuth, thallium, antimony, and aluminium has its structure entirely changed by annealing in sulphuric acid at about 250°. Nothing remains of the original structure, and the effect resembles that obtained by annealing steel castings at a bright red heat. The transformation of the structure of a metal at a temperature far below its melting point, and, in the case of the gold-antimony and gold-aluminium series, below the melting point of the *eutectic* alloys, in the presence of only two tenths per cent. of a foreign body, is probably not an isolated fact, and appears to open a new field for research.—A. W.

Binary Alloys containing Silver or Copper with another Metal, Complete Freezing-Point Curves of. C. T. Heycock and F. H. Neville. Proc. Royal Soc. 60, 160—161.

AN account is here given in abstract, of some experiments on the freezing points of alloys of two metals, one being in each case either silver or copper. The curve representing the freezing point in terms of percentage composition of the alloy, might either consist of two branches, each starting from the freezing point of the pure metal, and descending to the eutectic point, or, if a stable compound be produced, then the curve will be divided into two systems, with two eutectic points and an intermediate summit. An example of

the first case is illustrated by the silver-copper curve, and of the second case by that of copper-antimony, as proved by the investigations of Le Chatelier.

Of the alloys examined, the curve for that of silver-copper shows no indication of chemical combination except for an alloy of composition Ag_3Cu ; while in the case of silver-lead and silver-tin the eutectic alloy contains so little silver that the curve consists almost wholly of the branch starting from silver. The lead-copper alloy furnishes an illustration of the solidification of a system consisting of two conjugate liquids, namely, a saturated solution of lead in copper and copper in lead. The copper-tin curve presents features of interest: the rapid increase in the steepness of the curve as the tin is added, suggests the formation of complex molecules, possibly of the composition SnCu or Sn_2Cu , existing in solution; an abrupt change takes place when 15.2 atomic proportions of tin have been added—a fact in accordance with the observations of Behrens upon the great changes in the physical and microscopical character of the alloy. The curve between this point and that corresponding to 20 atomic proportions of tin is a straight line, indicating the existence of an isomorphous mixture of SnCu_4 and another compound, while the flat curve between 20 and 25 atomic proportions, may be due either to another case of isomorphism or the separation of conjugate liquids. Double freezing points occur between 15 and 20 atomic proportions.

A few experiments have been made on alloys of gold, nickel, and iron in copper; the latter two cause a rise, but the first a depression of the freezing point. Other investigations upon this subject are in progress.—V. H. V.

Blast Furnace, Obstructions in the. E. Barnard. Eng. and Mining J. 1896, 393—394.

"SCAFFOLDS" must be distinguished from obstructions in the crucible, which latter always arise from too low a temperature, while scaffolds occur when the furnace is hot and working regularly. Van Vloten's view—that scaffolds result from reduced carbon mingling with the charge and caking it—can hardly be maintained, for it postulates such a large quantity of carbon. More probably they are due to a refractory slag. A very basic slag may be looked upon, when melted, as a solution of the excess of base in a neutral or less basic slag of lower melting point. When the solid slag is heated it begins to soften and cake at or slightly above the melting point of the neutral slag, and is only completely fluid at a very high temperature. In the furnace the temperature rises from the throat to the crucible, and when working cold the temperature at which such a basic slag becomes pasty or cakes is only reached at the crucible, and no signs of fusion occur above; but when working hot, the temperature at the crucible is sufficient to melt the slag completely, and at some higher point, the temperature is such that the slag may cake, and thus block the furnace.

—J. T. D.

Iron and Steel, Note on Copper in. R. W. Raymond. Eng. and Mining J. 62, 293.

IN connection with the old idea that copper in small quantity acts detrimentally on steel, the author states the fact that the absence of any mention of copper and sulphur in some recent specifications would seem to indicate that the present process of steel manufacture guarantees the amount of copper present to be too small to be injurious. The actual limit is said to be still in doubt, and a few figures of early experiments are quoted in relation to the mechanical effect of copper on steels. It was formerly assumed that about 0.4 per cent. of copper would produce red-shortness in wrought iron, but instances are quoted of low-carbon steels containing 0.452, 0.849, and 0.862 per cent. of copper giving good welding results, and Howe quotes an instance mentioned by Choubley of a steel containing as much as 0.96 per cent. without serious red-shortness. In referring to the Holtzer copper-steels, shown at the Paris Exhibition of 1889, containing 3 to 4 per cent. of copper and possessing a high tensile strength and elastic limit with a considerable elongation, the author considers the data furnished to be incomplete, but that the conclusions seem to indicate that there was nothing to be gained in quality by the addition of copper to steel.—A. W.

Iron Alloys, Production of. Schrey. Berg. u. Hütten-Zeit. 1896, 55, 223.

ALLOYS of iron with nickel are made in Germany by adding pure nickel to the melted bath of iron in the Siemens furnace, or in the casting ladle, so that the nickel may not be carried into the slag. In France ferro-nickel is added in place of the pure metal, and in North America nickel oxide is used, mixed with lime for introduction into the open hearth or with carbon for crucible steel. For alloys, however, which are to contain more than 27 per cent. of nickel the pure metal must be added. The alloys cannot well be made in the blast furnace, because the crude product is not readily converted into a low-carbon, and therefore malleable material; as, on refining, it yields a brittle alloy, containing nickel oxide, which, however, may be made malleable by the addition of manganese, aluminium, or magnesium. Nickel steel is more fluid on pouring than is ordinary steel, and gives clean ingots, free from indications of liquation. Alloys containing up to 25 per cent. of nickel behave like ingot iron under the hammer or in the rolls; those containing as little as 5 per cent., are not easily machined, and the difficulty increases with the proportion of nickel. The ability to harden, depends upon the composition; it is absent in those samples which contain but little carbon, even though they are high in nickel; whilst those which contain more than 0.2 per cent. of carbon may be hardened, but this property is not affected by silicon. With higher proportions than 25—30 per cent. of nickel, the power of hardening is diminished, and carbon separates in the graphitic state.—W. G. M.

Cementation-Crucible Steel, Conversion of Siemens or Bessemer Steel into. S. Kern. Berg. u. Hüttenmänn. Zeit. 1896, 54, 235.

SOFT open-hearth steel, with less than 0.25 per cent. Mn. and 0.03 per cent. P and S, was cemented in chests, with the aid of the waste heat from reheating and puddling furnaces. The resulting steel, containing 0.85—1.15 per cent. C, was melted in crucibles with some wrought iron and a little ferro-silicon and chrome-iron ore, yielding a product with 0.95 per cent. C, 0.3 per cent. Mn, 0.04 per cent. P and S, 0.12 per cent. Cr, and 0.27 per cent. Si, which could be hardened well, and was adapted to the manufacture of tools, projectiles, and gun components.

—W. G. M.

Steel for Tram Rails, Composition of. Engineer, Oct. 30, 1896.

THE following is the specification, as regards chemical composition, of the street rails used in Syracuse, U.S.A.:—Carbon, from 0.53 to 0.63; phosphorus, not to exceed 0.095; sulphur, not to exceed 0.07; manganese, 0.80 to 1.00; silicon, 0.10 to 0.12.—A. S.

Copper Smelting: the "Direct" Method considered as the Future Metallurgical Treatment of Copper Ores, Argentiferous or Otherwise. C. James. Inst. of Mining and Metall. 1896 (39 pages).

AFTER a description of the ordinary Welsh process of smelting, reference is made to the use of the Baboon furnace, in which the roof of the melting furnace serves as the bed of a calciner, and it is pointed out that although there is an economy of heat in thus combining the two furnaces, the difficulty of preventing the bellying of the furnace in the middle, even when strong clamps are employed in its construction, and the greater frequency and extra cost of repairs, have led to its abandonment in most cases. Among the modifications of the Welsh process that are to be recommended, is the use of the blast furnace for making coarse metal and cleaning slags, and the employment of regenerative gas furnaces in place of ordinary reverberatory furnaces. In the latter case, not only is there an economy in labour and in fuel (the saving in the actual consumption amounts to 40 per cent., and the fuel itself may be of an inferior character), but there is a real saving of copper, which, as dust in charging or as splashes from the fused material, passes over into the grate and ordinarily is lost in the ashes of the solid fuel. An account

is given of the Continental and American methods of smelting, with a short description of the author's form of fore-hearth for the (copper) blast furnace. This consists of a reverberatory furnace, in which the metal and slag from the blast furnace are allowed to accumulate; these enter at one end, and the copper is tapped at one side, whilst the slag flows through the whole length of the furnace, and being thus kept hot and very fluid, passes off through a notch at the other end entirely free from shots of metal. The cost of calcining in automatic calciners of the O'Hara, Pearce, or Brown type is found to be one-third of that in the older furnaces, and at the same time the sulphur may be reduced to 5 per cent., as against 9 per cent., which is the minimum in the ordinary calciners. In bessemerising, the weak points are the destruction of the silicious converter lining, which is inevitable, and the mass of slag so produced, which contains too much copper to justify its rejection. Again there is a great loss both of copper and silver by volatilisation during the blow. These losses are acknowledged at 3 and 5 per cent. of the quantities of these metals respectively in the charge; but careful experiments in England point to an even greater loss than is admitted in the United States. But these losses occur only when metallic copper is present; hence some smelters have used the bessemerising process for the production of white metal, which is then finished in the ordinary roasting furnace.

In the direct method, a regulus containing from 70 to 80 per cent. of copper is first crushed, so as to pass a sieve with $\frac{1}{8}$ -in. holes; two-thirds of this is then roasted to oxide at a temperature below the fusing point of the sulphide, and is mixed with the remaining one-third portion, and the mixture is charged into a refinery furnace. The exact proportion between the two constituents of the charge depends upon the degree of calcination of the first portion. This is determined by a preliminary fusion of a sample of the mixture in a Cornish crucible; if the button of copper poured from the mixture be solid and flat, and covered more or less with regulus, it indicates that too much uncalcined regulus has been added; if, on the other hand, it be covered with an oxide of copper slag, it shows that too little was present. The extent of the oxidation during calcining depends upon economic considerations; the removal of the last portion of the sulphur in a charge is relatively the most expensive, inasmuch as a much longer time is needed for the purpose; hence the calcination of about two-thirds of the total weight of regulus without removing all the sulphur, is generally the most satisfactory. As soon as the mixture is charged into the refinery, the temperature is raised as quickly as possible. Reaction occurs on the surface first, and the reduced copper helps to conduct the heat downward to the remainder of the charge. The reaction is strongly exothermic, so that no extra fuel is required during this part of the process, and the sulphur dioxide in an especially pure condition (nearly free even from atmospheric nitrogen) may be utilised in vitriol chambers. The reaction over, the copper is brought to complete fusion, and is skimmed, but should be almost free from slag; it is then refined just as in the ordinary treatment of blister copper. The time required to work off the complete charge is about the same as that for refining; but the furnace used must be a little larger than those ordinarily employed for the same quantity of refined copper, although no greater weight of fuel is needed. Practice has shown that from 68 to 71 tons of copper may be obtained from 100 tons of white metal, as against about 50 tons by the old method; and in the cost of production, there is a difference of 13s. 9d. per ton of white metal in favour of the direct treatment. The cost of the preliminary treatment, being distributed over a larger ultimate output in the new process, becomes also reduced by about 24 per cent.

The special advantage of this process is that the oxidation is effected at a temperature below that at which the regulus fuses, instead of above it. But when matte or regulus is "roasted" (in the copper refiner's sense of the word) to copper, from 2 to 3 per cent. of the copper and from 5 to 8 per cent. of the silver present are lost by volatilisation. The author is certain that neither metal is lost during

calcination, and that no loss, therefore, occurs during concentration until metallic copper is produced. It is usually asserted that calcination causes a loss of silver, especially when the material contains arsenic, antimony, and zinc as impurities; but the author has found that in laboratory calcinations the calcining dish retains microscopic scales upon its surface which, on assay, make up the deficit of silver; and where calcination and sinterification are conducted in the same dish, no appreciable loss occurs. Hence the roasting process in the Welsh method involves a loss of copper and silver, which may be demonstrated by the use of condensing arrangements in the door of the furnace; in the direct process no such fumes can be detected, and there is no loss whatever of copper or silver. The reduction, in fact, is effected so rapidly by the reaction of the sulphide and oxide, that, although volatilisable compounds would tend to form at the temperature employed, there is no time for any serious loss to be incurred.

Under a recent patent (June 1896) the author now sometimes substitutes sulphide ores for white metal in the charge of the refinery, and with the Cape ore used at the Briton Ferry works a good result is obtained with a charge consisting of two of ore and three of calcined white metal. More refinery slag is produced, but this is no practical disadvantage, as it raises the pitch of the metal during smelting. Lumpy mattes may be satisfactorily treated without loss if silica be added to the charge; no silver or copper is lost, and the lead forms a silicate slag, from which the lead may be recovered in the blast furnace.

In starting new works for this process, the following course is recommended as embracing all the latest improvements and the results of the best experience:—Calcine and melt the bulk of the ore in reverberatory or blast furnaces, making coarse metal. Reserve sufficient of the ore, uncalcined, for cleaning all the rich slags of the works, and smelt this reserved portion with the slags in a water-jacketed cupola, again producing coarse metal. The coarse metal derived from both sources is crushed and calcined in automatic calciners, and the calcined product is melted in reverberatory furnaces to make white metal, which is then treated by the "direct" method.—W. G. M.

Gold Extraction. The Cyanide Process in the United States. Eng. and Mining J. 1896, 386—387.

THE cyanide process was introduced into America in 1889, and is yet in an experimental stage. Attempts to work the process with extemporised and insufficient plant are responsible for many failures. The chief requisite for success is fine comminution of the ore to pass at least a 40-mesh sieve (50 per cent. could then pass a 100-mesh), and that the metal be in a very fine state of division, as gold fragments of any considerable size are very slowly acted on by the cyanide. Neutral or slightly basic ores are best suited for the process, whilst those containing copper, ferrous sulphate, or other substances which consume the cyanide, are, of course, unsuitable. Many telluride ores give very poor results, and where the ore before lixiviation has been roasted to separate the gold and tellurium, the gold is often left in the form of compact globules which resist the cyanide. Any ore should be submitted to physical and microscopic as well as to chemical examination before its suitability for cyanide treatment is finally decided on.

Comparison between the cyanide and the chlorine processes, in the matter of cost, can hardly be profitably made, save in each individual case, as the circumstances of mechanical condition as well as composition of the ore, influence so greatly the applicability of the methods.—J.T.D.

Gold Recovery (Cyanide Process). The Siemens and Halske Process of. Eng. and Mining J. 62, 292.

BUTTERS states that the Siemens-Halske process is still successfully practised in the Worcester, Robinson, and other mines in the Transvaal, for the treatment of slimes and tailings, and a recent statement that it had been discarded is not true. Liquors containing 4 dwt. of gold per ton are reduced to 8 or 9 grs., and others containing 18 grs. are reduced to about 3 grs. per ton.—A. W.

Cyanide Process in the United States. G. A. Packard. Eng. and Mining J. 1896, 62, 341.

CHLORINATION is the only process which the cyanide method is seriously superseding. For mines located at a considerable distance from a railroad, the cyanide is said to be the better process—at least until the use of liquid chlorine becomes a practical success, as the cost of transportation of the chemicals used in chlorination has been hitherto high.

At the "Golden Reward" plant in South Dakota early in 1895, 35 lb. of chemicals per ton of ore were used for chlorination, while only $2\frac{1}{2}$ lb. were necessary for treating one ton with cyanide. If silver be present, the gold extraction is usually higher by chlorination than by cyanide, but by using the latter process, part of the silver is recovered. With amalgamation, cyanide enters into competition only in the case of very finely divided gold, which is saved more or less successfully in pans. The cost of cyaniding varies largely with the character of the ore. The lowest cost reported is 85 cents a ton. The cost of treating tailings has been reduced, at one plant operating under exceptionally favourable conditions, to 69 cents a ton. The tailings plants do not generally obtain a high extraction. Altogether, 200,000 tons of ore and tailings were treated by cyanide in 1895, producing over 1,000,000 dols. in bullion value.

—A. S.

Gold, Extraction from Slimes by the Bettel Process. Chem. Zeit. Rep. 1896, 251.

Among the various methods of treating tailings from the amalgamation mill, the McArthur-Forrest process has been very successful; but the whole of the tailings cannot be treated by it, owing to the impermeability of the slimes. Heating the slimes in order to render them porous, gives irregular results; and all dressing methods have failed, owing to the contained gold being so exceedingly finely divided. Bettel finds that the whole of this gold can be extracted by means of very dilute cyanide solutions. This special process consists solely in the manner of separating the solutions quickly from the slimes, and of washing the residue; it has been found capable of extracting 96–98 per cent. of the gold from slimes assaying 6 dwt. per ton, and 97 per cent. of that in concentrates; but it is only applicable to rich slimes with about $4\frac{1}{2}$ dwt. of gold per ton. Although a large number of operations have to be performed in conducting this process, they are simple and involve but little cost, as the material is circulated by means of a current of water or a steam jet.—W. G. M.

Gold. The Engelhardt Bromine Extraction Process in Operation. D. C. Pret and H. Trachsler. Eng. and Mining J., 62, 295.

THE so-called refractory ores of the La Plata Mountains, Colorado, which yield a low extraction of gold by amalgamation, have recently been subjected to experiment to ascertain which wet process could be commercially employed. The gold in the ore is chiefly combined with tellurium, whilst a small quantity exists in the free state. Cyanide of potassium was first tried, but was abandoned owing to the waste of cyanide by the copper present. In addition, also, to this metal, some of the ores contain arsenical iron pyrites, zinc blende, galena, and small quantities of chromic and titaniferous iron, so that the use of cyanide was out of the question. Consequently the process to be chosen was either that of chlorination or bromination, and the preference was given to the latter, owing, *firstly*, to the solvent power of the bromine solution being greater than that of the chlorine; *secondly*, to the quantity of chemicals required per ton of ore being less, and consequent saving in freight; and, *thirdly*, to the time required in applying the bromine solution in the barrel being less.

An analysis of an average sample from 100 tons of ore gave the following results:—Silica, 80.5; iron sesquioxide, 10.0; lime, 1.05; magnesia, nil; alumina, 3.7; and sulphur, 2.8; total, 98.05 per cent. The remainder, 1.95 per cent., is covered by small quantities of copper, arsenic, chromium, titanium, and tellurium, which are detected in solution after treatment. The gold contents vary from 1.25 to 2 oz., and the silver from 0.5 to 1 oz. per ton.

The latter is considered as scarcely sufficient to be noticed. The ore is roasted and charged into a lead-lined barrel containing bromine solution of an average strength of 0.25 per cent., although 0.15 per cent. may sometimes be employed with equal advantage.

After two or three hours' contact, the charge is lixiviated, and the excess of bromine got rid of by sulphurous acid. The gold is then precipitated as sulphide by sulphuretted hydrogen, and is refined in a manner similar to that used in the chlorination process. The average extraction varies from 93 to 96 per cent. of the total gold present.—A. W.

Sulphides [Silver, Gold, Copper], The Sulphuric Acid Process of Treating Lixivation. F. P. Dewey. Eng. and Mining J., 62, 293–294.

THIS is a description of the process as carried out at the Marsac Mill, Park City, Utah. It consists of six main operations, *viz.*:—(1) Boiling the sulphides with strong sulphuric acid in an iron pot; (2) Dissolving out the sulphate of copper and silver in a lead-lined tank, leaving a residue containing the gold and lead of the sulphides, and also rich in silver; (3) Precipitating the silver from the filtered solution by means of copper plates; (4) Sweetening, drying, pressing, and melting the cement silver; (5) Treatment of the solutions after the removal of the silver to crystallise the sulphate of copper and recover the excess of acid for re-use; and (6) Treatment of the gold-bearing residues. The silver contained in 116,519 lb. of sulphides amounted to 572,544 oz., and the amount obtained as fine bullion was 93.29 per cent. The remainder of the metal was divided as follows:—2.76 per cent. in the residue, 0.93 per cent. in the "cleanings," and 0.38 per cent. on hand, showing a "plus clean up" of 0.36 per cent.

The figures in respect to the gold recovery are not satisfactory, and this is attributed to the difficulty of determining the small quantities of gold in the presence of the large proportion of silver.—A. W.

Blende, Metallurgical Treatment, Reactions occurring in. E. Prost. Bull. Assoc. Belge des Chimistes, 10, [6], 246–263. (Second paper. See this Journal, 1896, 723.)

THE examination of the reducing action of carbon on the zinc in roasted blende was divided into the following series.

A. On zinc oxide alone, and in combination with the other free metallic oxides present.

Results.—In the first case the whole of the zinc is volatilised at about 1,075° C. When the zinc oxide is mixed in equal molecular proportions with ferric oxide, alumina, or lead oxide, the zinc is also volatilised at temperatures of 1,075° and 1,200°–1,250° C. respectively, so that the presence of these oxides does not increase the refractory properties of the zinc oxide.

B. On zinc oxide in presence of sulphur compounds.

For these experiments a chemically pure specular blende was employed, and the most favourable furnace temperature for the operation—in order to allow of the detection of any zinc sulphide formed—was determined by preliminary tests to be between 1,200° and 1,250° C., it having been found by such preliminary experiments that whilst within this range of temperature, zinc sulphide is not appreciably reduced, any zinc existing as oxide is completely volatilised.

The action of iron and lime on the liberation of zinc from combination with sulphur was first studied. In the case of iron, the action at any given temperature depends on the relative proportions of the iron and blende. The former should always be in excess of the theoretical quantity requisite for combination with the sulphur, the influence of temperature being demonstrated by the results of two tests with the same mixture (containing 150 per cent. excess of iron) at 1,200°–1,250° C. and 1,075° C. respectively. In the first test all the zinc was volatilised, whereas in the other a large quantity remained in the residue.

Lime has a much more energetic liberating action than iron, an excess of 75 per cent. over the theoretical quantity enabling all the zinc to volatilise at about 1,250° C.; and if a large enough proportion of lime be used, the same result may be attained at the fusing point of gold.

At the temperature of the tests (1,200—1,250° C.) no retarding influence on the reduction of zinc oxide appears to be exerted by calcium sulphate, even in presence of such bodies as silicate of lead and iron, which might convert the reduced calcium sulphide into silicate, and facilitate the formation of zinc sulphide.

On the other hand, magnesium sulphate, by reason of its different behaviour in presence of carbon at high temperatures, *viz.*, decomposition into magnesia and sulphur dioxide, favours the production of zinc sulphide, and it is fortunate that this sulphate is generally present in but small proportion in blends.

C. On the compounds of silica and zinc.

The result of experiments made with a mixture of zinc oxide, lead oxide, and silica heated together at 1,000° and afterwards reduced in presence of carbon at 1,200—1,250° C., seems to indicate that at these temperatures a certain proportion of an irreducible double silicate is formed, but when the temperature of the working furnace was employed, all the zinc was driven off. The simple silicate of zinc formed at 1,450—1,500° was totally reduced at the practical working temperature, and to within less than 1 per cent. at 1,200—1,250°, but when prepared at 1,550°, although completely driven off at 1,500°, was less readily so at 1,200—1,250° than in the former case.

The conclusions drawn from the results are: that no combinations are formed, during the reduction by carbon, which cannot be decomposed at the ordinary working temperature (1,450—1,500°) of the furnace. Furthermore, that it is highly probable that, by a judicious admixture of lime with the mineral, the loss (sometimes attaining to more than 4 or 5 per cent.) of zinc in the plumbaceous residues could be avoided. The intimacy of the mixture has an appreciable effect on the result of the reducing process, and the trouble of preparing the mixture with more than the ordinary care would be more than compensated if the yield were thereby increased by a few tenths of 1 per cent.

—C. S.

Lead and Bismuth, Solubility of Zinc in. Spring and Romanoff. *Zeits. Anorg. Chem.* **13**, 29—35.

A CRUCIBLE with a plug in the side was heated to regulated temperatures, varying from 250° to 900° C., as determined either by a mercury thermometer containing compressed nitrogen, or by calorimetric methods. Before being placed in the furnace, the crucible was filled above the plug with lead or bismuth, and a quantity of zinc placed on the top of the other metal, a layer of salt serving as a protection from the air. After long heating, with occasional stirring, a sample of the upper layer was taken, the melted metal run out by opening the plug, and a sample of the lower layer, remaining in the crucible, then taken. The analysis of these two samples gave figures representing the solubilities at different temperatures of bismuth or lead in zinc, and of zinc in bismuth or lead. Curves plotted from these figures show that the values of the reciprocal solubilities approach one another as the temperature rises, so that at a temperature of about 850° for bismuth and zinc, or 950° for lead and zinc, the values would be the same, or the metals would be miscible with one another in all proportions. The curves are analogous with those obtained by Alexejoff in the case of partially miscible liquids.—J. T. D.

PATENTS.

Gold, Impts. in Apparatus for Extracting, by Means of Mercury. [Use of Hydrogen.] J. W. Butler, London. Eng. Pat. 15,356, Aug. 15, 1895.

This is an appliance for forcing hydrogen gas on to the surface of mercury used in a revolving pan for extracting gold from ores by amalgamation, to prevent the surface of the said mercury from sickening or becoming oxidised.

—A. W.

Slimes or Tailings, Impts. in the Treatment of, for the Extraction of Gold or Silver therefrom by Means of Solvents, and Apparatus for that Purpose. John Cobeldick, London. Eng. Pat. 16,303, Aug. 30, 1895.

The various solvents, gases, and cleansing solutions are caused to circulate continuously through the mass of slimes by a forcing process, through the agency of the apparatus described.—J. H. C.

Copper, Zinc, Lead, Silver, Gold, and other Metals: Impts. relating to the Separation or Extraction of [Treatment with Chlorides and Chlorine, &c.], from Ores or Compounds containing the same, and to the Recovery of Chlorine used in the Treatment of such Ores or Compounds. H. R. Lewis, London, and C. Gelstharp, Manchester. Eng. Pat. 17,190, Sept. 14, 1895.

THE ore is roasted, if necessary, and then mixed, either in or out of the furnace, with a quantity of solid or liquid chloride of iron, or with hydrochloric acid, or some chloride. A quantity of water is added to the mixture in suitable vats, and chlorine gas passed into it, the whole being kept hot by steam or hot air. The mixture is then leached with water, containing acid if convenient, and washed with water until free from copper, zinc, or tin. The residue, if it contain lead, silver, or gold, is smelted or treated by any well-known process. The clear solution, after passing through a further quantity of ore, is run into covered vessels having one or more compartments, each containing anodes and cathodes. A current of electricity deposits the metal on the cathodes and liberates the chlorine at the anodes, ready for further use. The gold and silver which enter into solution are precipitated with metallic copper or zinc. The solution is then treated with a small quantity of oxide of copper or oxide of zinc to precipitate the iron, after which it is electrolysed to obtain the copper, zinc, lead, or tin.—A. W.

Aluminium Compounds [Carburized Aluminium and Alloys], Impts. in, and Means for Producing the Same. R. I. Roman, London. Eng. Pat. 17,250, Sept. 16, 1895.

To carburize aluminium, 99 per cent. of that metal is melted with 1 per cent. of calcium carbide, which latter is introduced in an aluminium cartridge into the molten metal. In order to remove the calcium, 16 parts of another alloy, consisting of 3½ per cent. of nickel, 3½ per cent. of tungsten, and 93½ per cent. of aluminium, are added to 84 parts of this mixture. When properly melted, the alloy is poured, and the calcium, together with any silicon and iron, remains at the bottom of the crucible in the form of a "slack." The metal so produced has considerable hardness, great elasticity, and a melting point lower than that of aluminium. Analysis shows the percentage of carbon to be about 0·1 per cent., but it is said that it may be as high as 1·5 per cent.—A. W.

Metallic Fumes, Impts. in Apparatus for Collecting. [Mingling in Suction Fan with Water.] J. Woolford, London. Eng. Pat. 17,320, Sept. 17, 1895.

To collect the metallic particles suspended in fumes after passing the ordinary cooling conduits and collecting chambers, a fan is introduced into the flue, provided with a nozzle through which water or a mixture of water and steam is injected. The water is broken up by the fan blades into a

finely divided condition, and, mixing with the fumes, washes out of them any metallic matter, which matter is afterwards collected by subsidence, filter-pressing, or otherwise.—A. W.

Gold and Silver, An Improved Process for the Extraction of, from their Ores. [Weak Alkali Hydrate and Carbonate.] F. C. May, London. Eng. Pat. 18,116, Sept. 28, 1895.

THE crushed ores are boiled in a mixed solution of alkaline hydrates and alkaline carbonates for at least one hour, and subsequently digested therein for at least 24 hours before amalgamation, so as to prevent the flouing or sickening of the mercury.—J. H. C.

Aluminium Alloy [Al, Ni, and W]. The Manufacture of a New. R. I. Roman, London. Eng. Pat. 21,186, Nov. 8, 1895.

THE alloy consists of 98 per cent. of commercial aluminium, 1 per cent. of nickel, and 1 per cent. of tungsten. Two methods of preparing this alloy are mentioned. The nickel and tungsten are first alloyed by adding the latter in the amorphous state, in a receptacle of aluminium, to the molten nickel, and then adding the aluminium. Or, an alloy of tungsten and aluminium is prepared by melting the latter metal with a mixture of tungstic acid and eryolite, so as to produce a metal containing 10 per cent. of tungsten. More aluminium is added in sufficient quantity for the final alloy, and the whole is added to the necessary amount of molten nickel. The alloy so produced possesses all the qualities of aluminium, as regards low specific gravity, ductility, colour, and resistance to corrosion, and has, in addition, a greater tensile strength and elasticity, a finer polish, and can be more easily machined.—A. W.

Sulphide Ores and Mattes. Impts. in the Roasting of. [Air or Air and Steam in Different Zones, &c.] C. F. Claus, London. Eng. Pat. 21,380, Nov. 11, 1895.

THE object of this patent is to bring, during the roasting process, the whole or most of the hot sulphurous acid gas produced by the oxidation of the sulphur contained in that portion of the ore charge which was last introduced into the furnace, together with air and some steam, into intimate contact with the other parts of the charge, which have already been partly or wholly roasted, in order to convert the oxides or remaining sulphides into sulphates. The furnace may be a vertical one, closed at the top with the exception of the charging door. The air enters through openings placed at different heights in the walls, and the sulphurous acid gas is withdrawn through an opening at the base. The ore in the lower portion of the furnace is first roasted, and the zone of combustion is then raised towards the top by introducing the air and steam through the higher openings. The products of combustion of the new ore at the top are then drawn downwards through the roasted ore at the bottom. In the case of horizontal furnaces, the same object may be attained by dividing them by partition walls into a number of chambers or compartments, connected together by means of valved passages, so that the gases may be supplied to and directed through any series of compartments according to the nature of the charge.

—A. W.

Soldering or Brazing of Metals, Impts. in, particularly applicable to Aluminium Alloys. F. A. Ellis, London. Eng. Pat. 22,041, Nov. 19, 1895.

THE bodies to be united (or one of them) are (or is) heated nearly, but not quite, to the melting point. The braze or solder employed, is composed of Al, 1 oz.; Sn, 1·3 oz.; Cu, $\frac{1}{2}$ oz.; Zn, $\frac{1}{4}$ oz. The copper is first melted, the zinc is added, then the aluminium, and finally the tin, the whole being stirred with a copper rod. For the process the claim is: "The preparation of one surface to be united with an aluminium braze, carefully amalgamating the same with said surface, and the completion of the brazed joint with another part by the casting of the latter part upon the former prepared part, to fuse the braze and make a homogeneous joint between them."—J. H. C.

Malleable Iron or Steel, An Improved Process and Means for Converting Pig Iron into. P. Sherk, J. L. Rutter, and S. Weiss, Lebanon, Penn., U.S.A. Eng. Pat. 18,981, Aug. 14, 1896.

A BLAST of air is variously applied to the molten metal in the manner and by means of the apparatus described, for converting pig iron into malleable iron or steel.—J. H. C.

XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

(A).—ELECTRO-CHEMISTRY.

[Potassium Percarbonate], Oxidising Substances, Electrolytic Preparation of a New Class of. E. J. Constan and A. von Hansen. Zeits. f. Elektrochemie, 3, 1896, 137—144.

WHEN carbonates of alkalis or of ammonium are dissolved

in water, they are dissociated into ions \bar{M}_2 and \bar{CO}_3 ; and when they are electrolysed we get at the cathode, hydrogen, and the hydroxyl compound of the alkali (or ammonium), and at the anode, oxygen and a bicarbonate. It might be expected that if water were added gradually to the solid carbonate, the dissociation would take place in stages, —

ions \bar{M} and \bar{MCO}_3 being first formed, and complete dissociation into three ions occurring on further dilution.

Under suitable conditions the ions \bar{MCO}_3 might unite into new molecules $\bar{MCO}_3 - \bar{MCO}_3$, just as persulphuric acid is obtained from sulphuric acid.

The authors find that this is the case. When a saturated solution of potassium carbonate is electrolysed, the evolution of oxygen at the anode diminishes as the temperature is reduced and ceases at -10° . In place of the crystalline precipitate of potassium bicarbonate, there is formed a bluish amorphous powder; this is potassium percarbonate, $K_2C_2O_6$. In order to obtain a good yield, the potash solution must be kept saturated. It is electrolysed between platinum electrodes in a beaker with a porous diaphragm, the beaker standing in a freezing mixture. 3—6 accumulators are used. Platinum wire is used as the anode and platinum foil as the cathode. The temperature must not rise above $9^\circ C$; the yield is best when it is kept below -15° . The percarbonate is quickly decomposed by water at the ordinary temperature. The suspended salt must therefore be quickly transferred to a filter, and then (without washing) placed on a porous plate in a desiccator over phosphorus pentoxide. On drying, it loses its bluish colour and becomes nearly white. The amorphous highly hygroscopic powder thus prepared always contains more or less bicarbonate and carbonate of potassium.

When slightly warmed, potassium percarbonate decomposes into potassium carbonate, carbonic acid, and oxygen—

In ice-cold water it dissolves almost without decomposition; when dissolved in water at the ordinary temperature it evolves oxygen and forms bicarbonate—

In presence of oxidisable substances it acts as an oxidising agent. It bleaches indigo solution, cotton, silk, and wool. It rapidly oxidises lead sulphide to sulphate—

Under certain circumstances potassium percarbonate also acts as a reducing agent. Thus the following reductions take place with evolution of oxygen—

This behaviour indicates that the percarbonate is really the carbonate of a holoide (Traube, Ber. 19, 1115), viz., potassium peroxide. Like the holoide of the alkalis, it is a reducing as well as an oxidising agent; and like the

hydroxides of the alkalis and alkaline earths, it produces hydrogen peroxide when acted on by acids (e.g., dilute sulphuric acid)—

Under similar conditions, rubidium percarbonate is obtained from rubidium carbonate as a white, exceedingly lygroscopic powder. The carbonates of sodium and ammonium are only very slightly soluble at low temperatures, and their percarbonates have not yet been isolated.

—D. E. J.

PATENTS.

Electrolytic or Galvanic Processes or Cells, Impts. in or relating to. H. H. Lake, London. From C. Hoepfner, Giessen, Germany. Eng. Pat. 17,745, Sept. 23, 1895.

In this process the bath is divided by means of diaphragms into anode and cathode compartments so that the latter are above the former, and anode cells communicate with anode cells, and cathode with cathode, as described in Eng. Pat. 13,733, 1890 (this Journal, 1891, 839, and 1892, 1015). To allow of the use of as low an electro-motive force as possible, soluble anodes are employed, which are formed of some metal or metallic substance which differs from the metal of the final product obtained at the cathode, and is readily precipitated from its solutions like lead, but is insoluble in diluted acid (especially in diluted sulphuric acid), so as to exclude the employment of zinc or iron for the anodes. These may consist of lead or plumbiferous substances, compounds, or alloys in a compact, pulverulent, or spongy condition; or of other metals, such as mercury or copper, or their compounds or alloys. The metals dissolved from the anodes are rendered insoluble by chemical or physical means, and their precipitation takes place preferably outside the anode compartment. The precipitates are collected and utilised preferably by regenerating the metal by the action of some reducing agent, such as coal-water-gas.

One or both of the electrodes may be removable, and that next the anode should preferably consist of a chloride, nitrate, or acetate—say the acetate of zinc, or of acids or salts capable of forming soluble lead compounds. The lye is circulated past the lead anodes, so that it never contains more than from 50 to 100 grms. of lead per litre, and this lead is precipitated by means of the salt or oxide to be indirectly decomposed (such as sulphate of zinc), thereby regenerating the electrolysed intermediate substance, such as acetate of zinc. Other precipitates may be employed, and the process can be applied to the method of depositing copper and zinc described in Eng. Pats. 18,080, 1890, and 11,724, 1894 (this Journal, 1895, 581), and to the production of many bodies by electrolysis.—G. H. R.

Plates for Electric Accumulators or Secondary Batteries, Impts. in and in the Manufacture of. [Potassium Sulphate Coating.] J. Korner, Mannheim, Germany. Eng. Pat. 19,745, Oct. 21, 1895.

To lengthen the life of the plates, the supports are subjected to the action of the current in a bath composed of a solution of potassium sulphate in sulphuric acid, when they receive a protective crystalline coating of the acid sulphate. When sufficiently coated, the supports are removed from the bath, and the paste of active material is applied to them, after which they are formed in a bath of the same composition, whereby each particle of the paste is also enclosed in a crystalline coating. When the cells are in use, the electrolyte must always contain potassium sulphate in excess.

—G. H. R.

Primary Electric Batteries, Impts. in or relating to. [Circulation.] W. Rowbotham, Birmingham. Eng. Pat. 20,828, Nov. 4, 1895.

This invention relates to that class of primary batteries in which the main body of the exciting and depolarising liquids is contained in reservoirs separated from the portion contained in the cells by perforated partitions which allow of the circulation of the exciting and depolarising fluid during the working of the battery, as described in Eng. Pats. 197,760 and 13,730 of 1895 (this Journal, 1896, 38).

In this improvement the battery consists of an outer case divided longitudinally into three main compartments, each of which is divided into four subsidiary compartments by means of three transverse partitions. The centre longitudinal compartments are each provided with a porous partition, between which the metal elements, preferably iron, are placed, while the carbon elements are in the outer spaces. Provision is made for the circulation of the electrolyte by means of tubes passing through the various portions, and an exhaust tap; or the various compartments may be thrown into communication as desired, by means of taps worked from the outside of the vessel by means of a rod. The carbon elements are immersed in a solution composed as follows:—

	Oz.
Bichromate of soda	32
Nitric acid	55
Sulphuric acid	150
Water	320
Potassium chlorate	4

The exciting fluid within the porous cell, consists of a solution of about 1 oz. of potassium chlorate to about 60 oz. of a saturated or diluted solution of ammonium chloride or potassium chloride.—G. H. R.

Electrodes, Impts. in, suitable for Electrolytic Apparatus. [Platinum.] C. Kellner, Vienna, Austria. Eng. Pat. 22,207, Nov. 21, 1895.

In order to give rigidity to the electrodes and to reduce the weight of platinum employed, they are constructed of thin-walled platinum tubes, in which are inserted or cast, accurately fitting metallic conductors. The platinum tubes may be provided with lateral rib-like projections, preferably serrated at their edges. These electrodes may be made bipolar by arranging them so that they extend through a wall of non-conducting material, as described in Eng. Pat. 9285, 1894.—G. H. R.

(B).—ELECTRO-METALLURGY.

Peroxide of Lead, Improved Method of Manufacture of. H. N. Warren. Chem. News, 1896, 74, 141.

LEAD ORE or sulphate of lead from vitriol tanks, &c., is introduced into canvas bags, through each of which is inserted a lead sheet. These bags are now immersed in dilute vitriol, and connected respectively to sheets of iron; the sulphate or other lead compound contained therein is thus speedily and completely reduced to the spongy metal, the bags being afterwards connected alternately by their lead plates and exposed to the action of an electric current, the positives being thus completely converted into peroxide, whilst the temporary accumulator thus produced is again emptied of its current into further quantities of spongy metal, thus producing a further quantity of peroxide. The author states that the process, when rightly conducted, yields an absolutely pure and cheaply formed oxide.—A. S.

PATENTS.

Metallic Zinc and Metallic Copper, Impts. in a Process and Apparatus for the Electrolytic Production of, from Zinc Ores containing Copper, and Oxygen Gas as a By-Product. C. A. Burghardt, Manchester, and G. Rigg, Eccles. Eng. Pat. 19,934, Oct. 23, 1895.

THE roasted and ground ores are treated in a suitable tank, provided with a mechanical stirrer, with a concentrated solution of ammonium carbonate, sesquicarbonate, or bicarbonate, or mixtures of these, or with a solution of ammonia gas. On stirring, the oxides of zinc and copper are rapidly dissolved out of the ore, and may be removed in solution after settlement or by filtration. The separated solution is heated to 40° C., and the iron is removed by means of hydrated oxide of tin and prolonged agitation. The copper is then precipitated by metallic zinc; finally the zinc is removed by electrolysis at a temperature of 40° to 50° C., oxygen gas being at the same time liberated from the positive pole. The tanks used may be of wood; they must not be of iron. The oxide of tin is recovered by dissolving the accompanying oxides of iron with sulphuric acid.

The ammonium salts accompanying the insoluble residues are recovered by washing with water.

The various solutions are covered with a layer of paraffin oil or other mineral oil of high flashing point and low viscosity, to prevent loss of ammonia by volatilisation.

—J. H. C.

Metals, Impts. in the Electro-Depositing of. [*Rapid Circulation.*] A. S. Elmore, Leeds. From J. O. Elmore, Kapurthala, India. Eng. Pat. 21,283, Nov. 9, 1895.

The object of this invention is to allow of much higher current densities being employed in the electro-deposition of metals than has heretofore been possible. This is effected by placing the anode close to the mandrel on which deposition takes place, and forcing a large volume of electrolyte through the interspace by means of a centrifugal pump or other suitable agency. The electrolyte may be admitted between the anode and cathode from the ends of the tank, or preferably through a perforated pipe or chamber running along the bottom of the tank under the anodes, which are so arranged as to allow a free space between the mandrel and the supply pipe.—G. H. R.

Impure Bismuth, Impts. in the Treatment of, for Refining the same. B. Zakorski, F. Hurter, and J. Brock, Liverpool. Eng. Pat. 22,251, Nov. 21, 1895.

THE impure bismuth is employed as an anode in an electrolytic tank with a solution containing nitric acid as an electrolyte. Carbon, pure bismuth, platinum, or other suitable material may be employed as the cathode. A current density of 15 amperes per sq. ft. of active bismuth surface is recommended, and the density must not exceed 30 amperes. Pure bismuth is deposited on the cathodes, from whence it falls, or may be easily removed. It is then washed with dilute HNO_3 , dried and fused. When the electrolyte has become too rich in lead, it may be freed from it by electrolysis, or the contained bismuth may be precipitated by metallic lead, and the resulting solution of lead nitrate utilised in any desired way.—J. H. C.

Metals, Improved Apparatus for the Electro-Deposition of. [*Polishing.*] A. S. Smith, T. A. Smith, R. J. Smith, S. Smith, and T. Deakin, Walsall. Eng. Pat. 5274, March 9, 1896.

THE polishing is effected by the rotation of a hollow barrel or drum, within which the work to be plated is placed. The drum, which is perforated to admit of the circulation of the electrolyte, is made of wood or earthenware, and is preferably octagonal in shape. It is mounted horizontally on a long sleeve or hollow hub provided with equidistant copper contact pieces, which are separated by wood or earthenware rings, which protect the metal from the action of the liquid. The hub and the barrel are mounted so as to rotate freely on a metallic bar supported on insulated brackets, and the apparatus is immersed in the bath, which contains the usual anodes. Suitable means are provided for rotating the barrel at any desired speed, and connection is made with the work contained in it by means of the contact pieces and the metal axis, which latter is connected to the negative pole of the source of electric supply.

—G. H. R.

PATENTS.

Soap, A New or Improved Process of Manufacture of Petroleum. S. E. von Graeve, Düsseldorf, Germany. Eng. Pat. 18,760, Oct. 7, 1895.

FAT (with or without the addition of wax) is heated to 100°C ., and nitric acid at a temperature of 100°C . gradually

added to it, with constant agitation, until the evolution of nitrous acid and volatile organic acids ceases. The product is dissolved in petroleum, and saponified with caustic or carbonated alkali.—J. J. K.

Soap, Impts. in the Manufacture of. J. W. Barclay, Eltham. Eng. Pat. 19,021, Oct. 10, 1895.

THE object of this invention is the incorporation in soap of solidified or thickened unsaponifiable oils, and thereby of disinfectants or insecticides dissolved therein. The unsaponifiable oil is solidified or rendered pasty (e.g., by treating with resin or alkali), and then incorporated with the soap at any stage in the course of its manufacture. In this way a better and more homogeneous soap is said to be obtained than if ordinary liquid oil be used.—V. C.

Filtering Apparatus [Wash Oil, &c.], Impts. in. C. Whitefield, Kettering. Eng. Pat. 19,968, Oct. 23, 1895.

See under I., page 792.

Detergent or Tanning Substance, New or Improved. [*Extract of Soap-Berry.*] P. C. D. Castle, Liverpool. Eng. Pat. 21,557, Nov. 13, 1895.

THE husks of the soap-berry (*Sapindus trifoliatus* L.) are macerated in water at 180° to 190°F . for seven hours, in the proportion of 1 lb. per gallon. The liquid is passed through strong, coarse silk and evaporated at a temperature not exceeding 190°F ., with the result, that a sticky resinous substance is formed which, at 60°F ., is as hard as beeswax. It "melts" readily in hot or cold water, and forms a lather which has more powerful cleansing properties than soap. It may be used in tanning.—W. G. M.

Soaps, Impts. in Liquid Disinfectant. J. B. McArthur, Newferry, Chester. Eng. Pat. 22,332, Nov. 22, 1895.

86 PARTS of 77 per cent. caustic potash are mixed with 250 parts of carbolic acid, tar oil, naphthol, or similar disinfectants, at 200°F .; 355 parts of oleic acid or other fatty material are then stirred in, and sufficient water added to produce a liquid soap containing 12 per cent. Another method is to saponify the fat first with alkali, and then dissolve the soap in the disinfectant.—J. J. K.

Separating Oil from its Volatile Solvent [Steaming]. Impts. in or appertaining to. G. F. Metzger, Cleveland, Ohio, U.S. Eng. Pat. 15,050, July 7, 1896.

THE ordinary process of removing naphtha by live steam leaves the oil with an objectionable smell, and a glutinous matter known as "foots" separates from the oil. These bad effects, which are due to the live steam being too hot and too dry, are avoided by the present invention, which consists in heating the solvent and its contained oil to the vaporising temperature of the former, and then injecting water heated to about the same temperature. The mixture is kept agitated, and the vapours are conducted away as they are formed.—V. C.

Separating Naphtha or other Volatile Solvent from Oil, A New or Improved Process of and Apparatus for. [*Vatdissolving by Steam from Large Surface.*] G. F. Metzger, Cleveland, Ohio, U.S. Eng. Pat. 15,597, July 14, 1896.

AFTER the extraction from crushed seed, the volatile solvent with its contained oil is heated in one receptacle, and a small body of water in another receptacle. A large proportion of the solvent is removed by the action of the steam upon the large surface exposed in a shallow trough, and the action is carried to an end by the further extension of surface caused by the subdivision of the oil into drops, which fall through the perforated bottom of the trough into the remaining water. Air is blown through the liquid, which, with a constant suction kept up by fans, accelerates the action and promotes the mixing of oil and water. During this part of the process, not only is the last of the solvent removed, but the oil is thoroughly washed and partially bleached.—V. C.

Soap, Impts. in Process and Apparatus to be used in the Manufacture of. W. F. Haywood, Austin, Ill., U.S.A. Eng. Pat. 16,746, July 28, 1896.

Soap is rapidly manufactured under pressure, the apparatus consisting of a horizontal jacketed cylinder, provided with an agitator, and valves for the reception of raw material and ejection of the finished soap. The charge of field fat and lye (the alkali in which is sufficient for complete saponification) is run into the cylinder and agitated, steam at 40 lb. to 60 lb. pressure being admitted at the same time to the jacket. When the temperature of the mass in the cylinder has risen to that of the steam supply, the air in the cylinder is expelled through a valve. The temperature will now be about 260° C., perfect saponification resulting in a few minutes; the soap is then ejected from the cylinder into the crutching pan.—J. J. K.

Fats, Oils, Resins, Sulphur, Colours, Tanning Materials, and the like; Impts. in or relating to the Extraction of, by Means of Volatile Solvents, and Apparatus therefor. J. Merz, Brünn, Austria. Eng. Pat. 16,766, July 28, 1896.

See under I., page 792.

Colour Wash or Distemper Paints, Impts. in the Preparation of. A. T. Hall, Hull. Eng. Pat. 23,155, Dec. 3, 1895.

"The preparation of colour wash or distemper paints" is to be "by mixing pigment, glue, or the like, linseed oil and oak varnish, with or without glycerin, and then oxidising them." "A disinfectant is added to this mixture." —F. H. L.

(B).—RESINS, VARNISHES.

PATENTS.

Cleansing Varnished and Polished Wood Surfaces, Compound for [Hydrochloric Acid and Glycerin], A New or Improved. C. E. Postlethwaite, Forest Gate, Essex. Eng. Pat. 12,930, July 4, 1895.

This compound is composed of a mixture of 70 oz. of hydrochloric acid and glycerin (in the proportion of 3 parts of hydrochloric acid to one part of glycerin), and 30 oz. of flour. The addition of 5 per cent. of albumin to the hydrochloric acid is said to impart an extra gloss to the cleansed surface of wood.—J. J. K.

Artificial Veneers, Improved Composition for the Manufacture of. C. Köster, Cologne. Eng. Pat. 16,999, July 31, 1896.

The claim is for "A composition for producing artificial veneers, consisting of a mixture of wood dust, zinc white, flour paste, resin size, linseed oil, and grape sugar or other similar saccharine matter." The composition on drying is said to be soft, elastic, and tough, and also to be waterproof.—A. S.

(C).—INDIA-RUBBER, &c.

PATENT.

Pneumatic Tyres, Impts. in Compositions [Glycerin with Gelatinous Silica or Alumina] for repairing Leaks in. C. S. Howe and J. W. Langley, Cleveland, U.S.A. Eng. Pat. 16,365, July 23, 1896.

A small quantity of the proposed liquid composition, within a pneumatic tyre, will act automatically, it is said, in repairing punctures in the india-rubber of pneumatic

tyres. Glycerin holding gelatinous silica or aluminium hydrate in suspension may be used. Three volumes of glycerin are mixed with one volume of liquid water-glass, an acid is stirred in, and the resulting jelly is incorporated with three additional volumes of glycerin. Four to six ozs. of such a liquid are sufficient for a tyre. To make the aluminous fluid, a salt of alumina, or an alkali aluminate solution, is incorporated with glycerin and neutralised by addition of an alkali or of an acid, according to the aluminium compound used, and the thick jelly formed is ground up with more glycerin to the consistency of a syrup. Instead of glycerin, water thickened with mucilage or dextrin, and in which an equal weight of calcium chloride is dissolved, to prevent evaporation, may be used.—E. S.

XIV.—TANNING, LEATHER, GLUE, SIZE.

PATENTS.

Tanning Hides and Skins, Impts. in Apparatus employed for. [Agitation.] L. A. Groth, Stuttgart. Eng. Pat. 18,879, Oct. 8, 1895.

In order to impart a reciprocating motion to the hides in the vats, they are suspended from laths attached to a series of independent frames, of which there is one to each vat. Above these frames are other larger frames worked by a crank and connecting rod. These upper frames are kept constantly in motion to and fro over rollers placed on the rims of the vats, and the smaller frames may be instantaneously connected to or disconnected from them by means of a simple clutch thrown into or out of gear by a lever. In this way each vat-frame with the hides may be kept oscillating as long as may be necessary, and may then be kept stationary without interfering with the motion of the hides in other vats. Electrical connections may be made, if desired.—W. G. M.

Detergent or Tanning Substance, New or Improved. [Extract of Soap-Berry.] P. C. D. Castle, Liverpool. Eng. Pat. 21,557, Nov. 13, 1895.

See under XII., page 817.

Lime, Process for the Removal of, from Hides and Skins, after Treatment in the Lime Bath. A. Brogard, Mörchingen, Lothringen. Eng. Pat. 23,310, Dec. 5, 1895.

The hides, after the removal of hair and flesh, are placed in a solution containing from 1.5 to 2 per cent. of sulphuric acid for about 1 or 2 minutes to extract the lime remaining from the effect of the lime bath. Dilute potash may be substituted for the acid.—W. G. M.

Whalbone, Artificial; Process for Manufacturing. W. Hunkemöller, Amsterdam. Eng. Pat. 13,242, June 16, 1896.

BONES are stripped of fat, the calcareous constituents are extracted with hydrochloric acid, and the residual cartilaginous substance is steeped in 15 to 30 per cent. chrome alum solution until saturated. It is then dried and cut into strips for use.—W. G. M.

Leather, Chrome-dressed, for Dyeing Purposes, Improved Process for Preparing. E. Avellis and E. Köster, Berlin. Eng. Pat. 16,600, July 27, 1896.

THE leather is first freed from acid by washing in water containing 3 per cent. of whitening and 2 per cent. of common salt. It is then immersed for about half an hour in a tannin liquor of 1° to 2° B. (for divi divi), or weaker for light tints. The leather may then be dyed at once, or to obtain clearer tints, it may be re-tanned with tartar emetic in the manner described in the specification.—W. G. M.

Glue, Liquid [from Leather Parings]; New or Improved Process for the Preparation of, for Joiners, Upholsterers, and the like. E. E. E. Martens, Neustadt-Holstein, Germany. Eng. Pat. 17,370, Aug. 6, 1896.

100 PARTS of the best glue, made from leather parings, are softened in 150 parts of water; 10 parts of salicylate of

soda are then added, and the mixture is heated until the solid has dissolved. 1 grm. of oil of cloves is finally added to each kilo. of glue. The whole remains liquid, and may be used, after dilution, as a substitute for gum.—W. G. M.

Tannin Extract, Improved Manufacture from Sulphite Cellulose [Waste Liquors] Lyes. M. Honig, Brünn. Eng. Pat. 18,265, Aug. 13, 1896.

THE ordinary lyes obtained by treating wood with calcium bisulphite cannot satisfactorily be used, it is stated, after the mere separation of the lime by sulphuric acid, by reason of the existence of free acids in the solution, and as only the tannin of oak is precipitable by lime from these liquors, the alternative method is restricted in its use. In this process, the sulphite lyes are first neutralised with calcium carbonate or with lime, so that they may be safely concentrated, after clarification by deposition, to 15° – 18° B. They are then heated in lead-lined boilers with sufficient sulphuric acid to combine with the lime contained in the lye; or other acids capable of forming lime salts soluble with difficulty, may be used instead of sulphuric acid. The heating is here continued until all volatile acids are expelled. The precipitated calcium sulphate is filtered off, and the filtrate is brought up to 28° – 30° B. in a vacuum pan. After clarification by deposition, the solution may be used as a tannin extract.—W. G. M.

XV.—MANURES, Etc.

Fertilisers and Anti-Fertilisers. Imp. Inst. J., November, 1896, 409.

RESEARCHES* have shown that a calcareous soil is advantageous for the growth of pine trees, the most conspicuous effect produced by a deficiency of lime being the production of short needles. If, however, magnesia is present with the lime, it acts injuriously, unless the relative proportion is very small. This last fact has been amplified by other experiments;† these show that it is only the chloride of magnesium which is injurious, the other and less soluble salts being probably innocuous in the presence of lime.

The latter is also of great use as a manure for tobacco, when grown on soils poor in this ingredient. The combustibility is thereby considerably increased, potash not being so useful for this purpose as was supposed.‡

The disappearance of nitrates from soils is a matter of considerable importance, and has met with some attention. It has been found that certain kinds of manure, if used together, caused a great loss of nitrogen,§ and this was attributed to denitrification by ferments. In 1890 the presence of such denitrifying agents in straw and other vegetable substance was demonstrated, and it is now experimentally proved that soil when watered with a preparation of these germs rapidly loses nitrogen. A similar result can be produced by consolidating the ground so as to check aeration.¶

The influence of various chemical reagents on germination has been studied. An elaborate paper on this subject has been published, containing the results of 275 experiments, arranged in 17 series.** The more important conclusions may be summarised as follows:—Mineral and organic acids are injurious to germination, and strongly acid salts are more injurious than neutral salts. Free bases and strongly basic salts are poisonous. Salts, generally, are either injurious or without effect. Fats and ethereal oils prevent the germination of corn, and much retard peas and rape. Anaesthetics and hydrocarbons, generally, retard germination, while their vapours kill the seeds. Organic antiseptics are all injurious in solutions of more than 0.1 per cent., and coal-tar dyes also in solutions of 0.05 per cent. The influence of the various constituents of artificial manures in solutions of 0.05 to 0.5 per cent. has been examined.†† It is found that they are injurious

to germination, but grains are more resistant than other seeds to their action. Lime water and basic phosphates, however, are very beneficial, especially to leguminous seeds. Sulphuric acid, even in very dilute solutions, is highly injurious, and as a considerable quantity (0.108 to 1.612 per cent. by weight) is produced in the germination of seeds, it seems evident that it is the power which lime possesses of combining with, and neutralising, this acid that is the secret of its value.

New Phosphate Discoveries in Tennessee. Eng. and Mining J., Oct. 31, 1896, 418.

See under Trade Rep., page 837.

PATENT.

Phosphates of Ammonia and Potash, Process for the Manufacture of, in an Alkaline Mixture suitable for Manure. T. Jamieson, Glasterberry, N.B. Eng. Pat. 18,635, Oct. 5, 1895.

DRY superphosphate is stirred up with about an equal quantity of ammonium sulphate or potassium sulphate, or a mixture of the two salts, to which has been added a proportion of water insufficient to dissolve the salts. Just before the mixture thickens, some dry organic substance, such as bran, sawdust, &c., is mixed in, and, after solidification, a further proportion of the drier is added, which has been previously caused to absorb sufficient potassium carbonate solution to give a slight alkaline reaction to the finished product, to which bone-dust or the like may be added, if desired.—E. S.

XVI.—SUGAR, STARCH, GUM, Etc.

Sugar Industry, Progress in, for the Second Quarter of 1896. Dingl. Polyt. J. 1896, 302, 40–46.

Aqueous Digestion.—Since the publication of Pellet's method (this Journal, 1896, 716) for the determination of sugar in beetroot by aqueous digestion, many investigations have been made to decide whether this method gives results in agreement with the alcoholic method in use. From E. Becker's results (Die Deutsche Zuckerind. 1896, 21, 1057) it appears that the aqueous digestion cannot replace the alcoholic, and that there are conditions under which the aqueous method may give results as much as 1 per cent. over the alcoholic digestion, the chief cause being due to the fact that, from the abnormal conditions of growth during the dry summer of 1895, a quantity of optically active non-sugar was produced in the beet, which is not precipitable by acetate of lead alone in aqueous solution.

Action of Acetic Acid on Sugar Solutions.—Xhonneux (Zeits. Ver. Rübenzuckerind. 1896, 46, 469) draws attention to the preservative action of 1 per cent. solutions of acetic acid. The solution is said to keep much longer if lead acetate is also present.

Magnesia in Limestone.—The method of Prinsen-Geerlig for the determination of small quantities of magnesia in limestone has been improved by A. Herzfeld and A. Förster (Zeits. Ver. Rübenzuckerind. 1896, 46, 284). After separating silica in the usual manner by evaporating to dryness with strong hydrochloric acid, the chlorides are redissolved in water and a few drops of hydrochloric acid. A few drops of nitric acid are added and the solution boiled, and then precipitated chalk added until a small quantity remains undissolved. The mixture is boiled and filtered. The test-tube containing the filtrate is now almost filled up with clear lime water, closed with an india-rubber stopper, and shaken. If much magnesia be present a precipitate forms at once, with smaller quantities after a few minutes. In the quantitative estimation this precipitate is dissolved in hydrochloric acid, neutralised, the traces of lime removed as oxalate, and the magnesia precipitated as phosphate.

Instantaneous Saturation.—The all but instantaneous saturation is, according to W. Guerrero (La Suc. Ind. 1896, 31, 161), preferably employed in the saturation of sugar juices with carbonic or sulphurous acid. In this arrangement the distributing pipes for the gas are placed one above the other in a spiral, so that the gas issues, not in one plane,

¶ Béal, Ann. Agron. 1892.

** Béal, Ann. Agron. 1896, 22.

†† Sigmund, Landw. Versuchs. Stat. 1896, 47.

†† Claudel and Crochetelle, Ann. Agron. 1895, 22.

but in several. The advantages are:—1st. Saturation of a larger quantity of juice with a smaller number of saturators. 2nd. Possibility of the saturation of very dense juice, otherwise difficult. 3rd. A more thorough purification by the calcium carbonate, and a greater decolorisation of the juice. These distributors are in use in the Spanish sugar works of Atarfe and Aleolea, where two saturators are now doing the work of three.

Purification of Juice by Electricity.—A Bandy (Oester. ungar. Zeits. Zuckerind. und Landwirth. 1896, 35, 238) makes an interesting communication on the working of the electrolytic method of Schollmeyer and Huber in the Russian sugar works, Stepanowka and Waronowitza.

After the diffusion juice leaves the measuring tank, $\frac{1}{4}$ per cent. of lime is added, and it is passed through a heater to be heated to 80° C. It is then electrolysed in a rectangular reservoir with zinc electrodes. A gradually thickening mud forms and a sticky deposit on the cathodes, which would cause great resistance to the current unless removed from time to time by reversing the current, when it falls off. In 15 to 20 minutes, the juice, now of a fine yellow colour, is passed to the saturators. From this point onwards, the action of the electrolysis is seen in a saving of 40 to 50 per cent. of lime, less foaming and consequent saving in grease of 60 to 70 per cent. The filter presses work better and give 20 to 25 per cent. less cake, so that there is a saving in cloths, in wash water, and in labour. The evaporation is easier, the massecuite freer and more easily centrifuged. For a daily work of 409.5 tons of beet, a current of 850 amperes at 5.5 volts suffices, requiring a motor of a little over 7 h.p. The author calculates that on working up 32,800,000 kilos. of beetroots there is an actual saving by electrolysis of 14,470 roubles. The tests have plainly shown that the use of electrolysis alone as a method of purifying raw juice is impossible, as it is irrational to place the more expensive electricity in opposition to cheap lime. Schollmeyer conceived the happy idea of employing them in conjunction, and herein lies the secret of the results of his process.

Electricity, instead of opposing, now completes the action of the lime, and acts, moreover, on certain parts of the non-sugar which lime, even used in large quantities, could not affect. Electrolysis precipitates almost three times the nitrogenous matters that are removed in the ordinary separation.

The Ranson Process.—This process, which has for its object the obtaining direct of the whole of the sugar contained in the beet juice as a white product, and thus seems called upon to render the further existence of refineries impossible, has given occasion in France for various communications, which, however, do not clear up the matter. The process was tried in the Beaumont Sugar Works in February 1896, with such success that according to Renard it is now to be introduced on the large scale. The process, as given in the French Pat. 284,831, is as follows:—The characteristic agent is barium peroxide (BaO_2), by which colouring matters rich in oxygen are reduced, and those poor in oxygen oxidised, in so far as the reduction of the former has not become superfluous by the employment of sulphurous acid. To beet and cane juices and liquors, 2 to 5 per cent. of barium peroxide are added in the form of a milk of 20° to 25° B., and allowed to stand until the escape of gas ceases. The barium peroxide decomposes, yielding oxygen in an intensely oxidising form, and barium oxide (BaO), which combines with sugar to form barium saccharate. The saccharate remains dissolved in the excess of sugar juice. The solution is sprayed under pressure into a closed vessel filled with carbonic acid, barium carbonate and sugar solution being obtained, the latter of such purity that it may be at once worked up into refined without the loss of more than $\frac{1}{2}$ per cent. of sugar. It is merely necessary, as some barium always remains in solution, to determine the quantity, and then to precipitate it quantitatively by sulphuric acid of known strength and afterwards with soda. The barium carbonate, by the action of nitric acid, gives carbonic acid, which is used for precipitation of further juice containing barium, and a solution of nitrate. The latter is evaporated to dryness and ignited in special

furnaces, yielding nitric acid, which is used again, and baryta, which is used, as before, to treat fresh quantities of the juice to be purified.

Du Beaufret (J. Fabr. de Sucre, 1896, 37, No. 18) attributes the action to the baryta, and not to the peroxide, whilst Verbière (*loc. cit.* No. 19) denies this, and remarks that Ranson aims, not at purification, but at decolorisation. Von Lippmann (Die Deutsche Zuckerind. 1896, 21, 1058) remarks that the most difficult and costly part of the regeneration, *viz.*, the conversion of barium oxide into peroxide, is not explained in the patent.—L. J. de W.

Sugar House Products, Determination of Viscosity of. Jaglenczky. Bull. de l'Assoc. des Chimistes de Sucre, et de Dist. 1896, 14, 239–240.

The analytical figures of the laboratory afford only incomplete information of the yield of sugar and molasses from a massecuite; for two massecuites apparently of the same composition, when centrifuged, give different results. Such differences depend not only on the chemical composition of the syrups, but also on their physical properties, notably their viscosity. The author recommends the Reischauer-Aulby viscosimeter; the determination is carried out by observing the length of time taken by 100 or 200 c.c. of the syrup to flow from the tube of the apparatus. The fluidity of water is taken as 100, Z and Z' the time of flow of water and the liquid under observation, the viscosity of the latter being expressed by the proportion $X = 100 \frac{Z'}{Z}$. —J. L. B.

Juice and Syrups, Relations between Evaporation and Viscosity of. Claassen. Centralbl. für die Zuckerind. der Welt, 1896.

It is well known that dilute solutions of sugar are more readily evaporated than concentrated solutions, other conditions being similar; but no commonly accepted explanation has yet been deduced from experimental data. The author has conducted his experiments in the laboratory, for the problem cannot be satisfactorily solved by working on a large scale, weak and strong juices being evaporated under different pressures and temperatures.

In the transmission of heat through a liquid, it is of great importance that the solid and liquid particles on the surface should change position rapidly. Steam bubbles must also be removed from the sides and bottom of the heater, for so long as they cover the heated surfaces, no transmission of heat can take place. The movement of a liquid and of its particles is dependent on the viscosity, and as it is known that a relation exists between this property and the rate of evaporation, the author conducted his experiments for the elucidation of this point. The apparatus used by him consisted of a Fischer's viscosimeter and of an evaporator. The weight of water evaporated, the temperature both of the heating steam and of the boiling liquid, and the duration of the experiment, were determined. The viscosity tests were made at 100° C., water being taken as unity. Solutions of molasses, massecuites, and sodium chloride were examined; the data obtained from the first two of these show that the coefficients of calorific transmission of the denser solutions diminish proportionately as the specific heat is lowered and as the viscosity coefficients are raised.

It then, obviously, became necessary to establish which of these factors, viscosity or specific heat, influenced the transmission of heat; and to this end experiments were made with solutions of sodium chloride. A series of tabulated results shows that in concentrated solutions the coefficients of calorific transmission, unlike those of massecuites and molasses, increase with the viscosity; that the specific heat of concentrated solutions is lower than that of dilute solutions or of water; whence it is concluded that the specific heat of boiling liquids has a very slight influence on the transmission of heat. From these results the author considers that it is no longer possible to ignore the influence of the viscosity of solutions upon the transmission of heat.

—J. L. B.

Low Products, Process for Boiling and Crystallisation of. F. Sachs. Bull. de l'Assoc. des Chim. de Sucre et de Dist. 1896, 14, 183—187.

THE author describes a process invented by R. Sachs, which has been successfully employed in a Russian factory. The syrups from first runnings are quickly worked into grained massecuites. On cooling, these massecuites yield a quantity of sugar, so that the syrups from the centrifugal machines have the composition of molasses. The green syrup from first runnings is boiled *in vacuo* until the sugar completely separates in crystals of medium size. About one-half of the product at this stage is allowed to flow into a mixer, and boiled with fresh syrups. If, at first, crystals are not deposited in sufficient quantity, they are certain to separate on the addition of new syrup. The process is equally suitable for the working of refinery products.—J. L. B.

Sugar, Methods of Manufacturing directly-consumable. J. de Gröbert. Bull. de l'Assoc. des Chim. de Sucre et de Dist. 1896, 14, 166—171.

THE methods in use to obtain a directly-consumable sugar, may be divided into two categories, namely, to treat the syrups resulting from the working of beetroot or cane as refinery clairess, or to transform raw into refined sugar by more simple and economical means than those employed by refiners. The chief obstacle to the direct manufacture of refined sugar is the coloration of the initial products. Many patents have been taken out for decoloration, and sugars of good appearance have been prepared. But the economy realised in avoiding boiling to grain, and centrifugalising, is more than counterbalanced by the cost of decolorising agents and the indifferent yield and quality of the products.

Agglomerated sugars, prepared by powdering a raw product of sufficient purity, mixing with a little water or clairess, and running into moulds, are condemned by the author, such products being dull in colour, and not homogeneous in structure.

Wulff has shown that if a mutilated sugar crystal is placed in a saturated solution of sugar, it exerts a selective action on the molecules of sugar in solution, and before any increase of size occurs the crystal assumes its typical form. This circumstance led Prangey to devise the following process:—A grained white sugar of good quality is powdered, and the sifted product mixed with sufficient saturated clairess for the mixture to have the same composition as a refinery massecuite. It is then led into a double-jacketed apparatus furnished with an agitator, and heated from 95°—100° C. by slack steam. When this point is reached the temperature is allowed to drop slowly to about 90°, and the mass then satisfies all conditions which characterise the ordinary refinery massecuite: that is, it consists of uniformly developed crystals of the same size, separated by a saturated syrup, which, in the course of working, behaves like the mother-liquor of a refinery massecuite. The mixture, after being run into moulds, is centrifugalised and treated in the manner commonly applied to refined products.—J. L. B.

Sugars, Production of Carbon Dioxide during the Decomposition of. [Bearing on Fermentation, &c.] Berthelot and André. Comptes rend. 123, [16], 567—580.

THE sugars subjected to examination were dextrose, levulose, galactose, and maltose; dilute hydrochloric, sulphuric, or phosphoric acid being the reagents employed—the latter being in some instances preferable, since it neither distils with water nor exerts any oxidising action.

Three methods were pursued: (1) Heating in sealed vacuum tubes at a temperature of 100° C.; (2) Distillation in flasks with inverted condensers; and (3) The same with ordinary condensers, the water distilled being replaced by an equal volume. The products examined were: unaltered glucose, carbon dioxide, carbon monoxide, humic acid, formic acid, levulinic acid, furfuraldehyde, and water.

In the experiments with sealed tubes a constant temperature of 100° C. was maintained for 644 hours, the products being analysed after 115 hours' and 168 hours' treatment, as well as at the end of the reaction. Phosphoric acid (16.78 grms. to 19.5 grms. of water) was employed as reagent.

Water.—At the first and second stages the loss of oxygen and hydrogen unrecovered, may be due to the formation of water or carbohydrates, but at the final stage must be regarded as water eliminated as a result of the formation of humic, levulinic, and formic acids, the proportions being O, 19.42; H, 2.35 per cent. of the total glucose taken.

Glucosan.—The results obtained point to the formation of glucosan by dehydration in the preliminary stage of the transformation of glucose.

Furfuraldehyde could not be detected among the products in this series.

Formic (11.90 per cent.) and *Levulinic* (39.88 per cent.) *Acids.*—In the theoretical decomposition of glucose into these acids and water, the ratio of the carbon in the first-named to that in levulinic acid is 1:5, so that the actual ratio (1:3.3) obtained in these experiments points to some other reaction as the source of about one-third of the formic acid found, corresponding, in fact, to the formation of *Humic Acid* (23.60 per cent.). In presence of phosphoric acid there appears, however, to be no connection between the formation of humic and levulinic acids, their ratio being irregular. Thus, at the end of 115 hours, some two-thirds of the final total of the former acid, against scarcely one-half of the latter, had been formed; and whilst after 168 hours the formation of humic acid had almost ceased, the production of levulinic acid still continued. On the other hand, when strong hydrochloric acid is used, nearly the whole of the glucose is converted into humic acid in 25 hours, levulinic acid having apparently not had time to develop under these circumstances. No definite relation could be detected between the amounts of humic and formic acids produced in 25 hours under the influence of hydrochloric, sulphuric, and phosphoric acids in different degrees of dilution.

Carbon Monoxide (1.19 per cent.) was shown by a separate test to be derived in part from formic acid, none being formed from levulinic acid.

Carbon Dioxide (2.07 per cent.)—The greater part (1.47 per cent.) formed during the first 115 hours; the increase during the remainder of the time is partly attributable to the gradual decomposition of humic acid. By heating glucose *in vacuo* with strong HCl to 120° C., the evolution of CO₂ and CO was found to increase progressively with the duration of the reaction.

In the distillation tests, which were performed by the aid of all three reagents, and in presence of air or hydrogen, the chief difference in comparison with the sealed tube experiments was the increased and more rapid formation of carbon dioxide, which, however, did not, as was proved by direct experiments, proceed either from oxidation or from the decomposition of levulinic acid. As regards the other products, the volatile acids were formed more extensively by sulphuric than by phosphoric acid, whereas the amount of humic acid was fairly constant under similar experimental conditions, the results, as a whole, pointing to the simultaneous occurrence of various congeneric reactions of such a nature as to be readily influenced by slight modifications in the conditions.

The other glucoses behaved in a similar manner, furnishing approximately equal quantities of carbon dioxide, small amounts of furfuraldehyde being also constantly produced in the distillation tests. The larger amount of humic acid yielded in a given time by levulose, as compared with the other glucoses (observed by Tollens and Grote), was found to be merely due to the more rapid rate of decomposition of this sugar, the total amount of the acid formed at the end of 24 hours' reaction with strong HCl being nearly the same for all.

The glucoses being formed by the synthetic accumulation of several simple molecules of methyl aldehyde, constitute systems of a low degree of stability, which accounts for their endothermic characteristics, and renders them liable to undergo various simultaneous reactions. For example, they may polymerise, disengaging heat from the union of several molecules, and the formation of stable compounds, such as water: glucosan and humic acid being produced in this manner. Again, by the action of dilute acids, the glucoses are converted into formic and levulinic acids and water, the first of which may be regarded as due to the separation of the carbon of the last molecule of methyl

aldehyde, and the concurrent deoxidation of the other five. Finally, this separation of oxygen may proceed further, the result being to convert the last molecule of aldehyde into carbon dioxide and hydrogen. This reaction always occurs, but is heightened by prolonged distillation and an increase in temperature above 100° C. Part of the hydrogen becomes fixed in the formation of humic acid, and it is probable that the tendency of the last molecule of aldehyde to separate may explain the formation of furfuraldehyde, which seems to indicate the production of traces of the pentoses during the decomposition of the glucoses.—C. S.

Molasses or other Sugar Solutions, Extraction of Sugar from. Langen. Monit. Scient. 1896, 47, 775—776.

The process consists in treating molasses or other syrups with barium hydroxysulphide, and recovering from the residues the whole of the sulphur as sulphurous or sulphuric acid, the latter being used to recover the barium from the saccharate and residues.

The sulphite and sulphate of barium thus obtained are then converted into barium hydroxysulphide by calcining with carbon. The solution from which the saccharate has been removed contains the barium which has not been precipitated as saccharate, as well as all the sulphur of the barium hydroxysulphide originally used. By treating the solution with concentrated carbonic acid, the barium is precipitated as carbonate, and sulphuretted hydrogen gas is disengaged. The sulphuretted hydrogen is converted into sulphurous or sulphuric acid by burning it, and the barium carbonate by these acids into sulphite or sulphate.

Magnesium sulphite or sulphate may also be used to decompose the barium saccharate, but as the magnesium hydroxide is difficult to filter, it is converted into carbonate. The magnesium may be easily separated from the barium salts after conversion into sulphite or sulphate.

—L. J. de W.

Saccharose, Purification of, and Recovery of Sugar from Solutions of. A. Wohl. Monit. Scient. 1896, 47, 766—775. (See also this Journal, 1896, 125, 287, 550, and 551.)

PRACTICALLY speaking, no process is known for the complete recovery of saccharose from its solutions by the formation of lead saccharate. Dubrunfaut (Dingl. Polyt. J. 1850, 138), in describing his baryta process, remarks that it is necessary "to maintain the oxide of lead for a long time in contact with the liquid, and even then it only fixes the sugar incompletely."

The fact that it is possible to convert more or less pure solutions of saccharose almost instantaneously and completely into lead saccharate, has hitherto escaped attention, from a number of conflicting causes.

The red litharge of commerce, finely pulverised and sifted, has scarcely any action, while the yellow combines at once, even at the ordinary temperature. By heating basic carbonate of lead to 200° or 300°, mostly red litharge is obtained, whilst by raising the heat to dull redness (about 600°) for a short time, and cooling quickly, it is obtained of a sulphur-yellow colour, soft and porous.

The combination of the oxide of lead with sugar to form di-saccharate of lead is assisted by heat in more concentrated solutions; with dilute solutions heat retards the reaction. A 50 per cent. solution heated for 15 minutes to 90° yields 95 per cent. of its sugar, while a 20 per cent. solution under the same conditions gives up only 35 per cent. This phenomenon is due to the fact that the solubility of the saccharate increases with the concentration of the solution of saccharose, and diminishes with rise of temperature.

The best temperatures are, for a 50 per cent. solution, from 80° to 50°, and for a 20 per cent. solution, 40° to 50°.

When impure solutions of saccharose are used, not only the sugar, but the non-sugars react, the lead oxide forming principally basic salts of lead, alkalis being liberated. This action is prevented by previous addition of potash or soda, and even dilute solutions may be desaccharified more quickly and completely if a small quantity of alkali be added and the temperature be not too high.

Ordinary beetroot molasses require 1 to 2 per cent. KOH and 75 per cent. of yellow oxide of lead calculated on the

molasses. Without heat the sugar is removed so completely in two hours that the liquor becomes levo-rotatory. The same result is reached in less than five minutes by employing 100 per cent. of PbO. Molasses containing 50 per cent. of sugar requires theoretically 66⅔ per cent. If the oxide of lead be not properly calcined—that is, if it is too hard, or if it be of a dark-yellow instead of a lemon-yellow colour—its efficiency may be reduced to 20 per cent., and the more so as it contains more of the red oxide.

To complete the reaction, it is merely necessary to stir until the mixture becomes homogeneous; as soon as it begins to thicken, its viscosity prevents further mixing. Methods of obtaining PbO in the wet way are also given.

The saccharate is next purified by filtration, after dilution with water at 10° to 50°. Above 60° the quantity of sugar dissolved, increases rapidly with the temperature. The washed lead saccharate is decomposed by saturation at 70° to 80° C. with carbonic acid gas, taking care to maintain the gas in intimate contact with the saccharate by suitable agitation. As the sugar passes into solution, the mixture becomes more fluid, and when saturation is complete, the volume of the deposit has diminished by a third. The final point of saturation is determined, not by titration, but by the polariscope, the current of gas being interrupted when the sugar content ceases to increase, the lead precipitate having still a strongly alkaline reaction. A further supply of gas would set at liberty non-sugars and reduce the quotient of purity.

The decomposition of the lead saccharate may be advantageously combined with other operations. It has been previously proposed to prepare lead saccharate from pure sugar, and to treat with the saccharate the juice to be separated, and to precipitate the excess of lead by sodium-calcium phosphate, but it is not necessary to have recourse to pure sugar.—L. J. de W.

Arabinose, Action of Water and Acids on, at an Elevated Temperature. Berthelot and G. André. Comptes rend. 1896, 123, 625—631.

The following observations were made:—

1. Dilute aqueous solutions of arabinose are not decomposed when cautiously boiled. If heated, however, to 200° C. in a sealed tube, furfural is produced in considerable amount (30 per cent.).

2. Arabinose, when heated to 100° C. in a sealed tube with hydrochloric or phosphoric acid, yields a large (15—55 per cent.) proportion of blackish humin substances (humine acid), and as by-products, variable quantities—depending somewhat on the concentration of the mineral acid employed—of carbon dioxide (1—2 per cent.), carbon monoxide ("traces" to 1.6 per cent.), formic acid (1—3 per cent.), and fixed acids. The humin substance formed, closely resembles in composition, &c., that obtained by the action of acids on glucoses, or by the polymerisation of furfural. Similar results, as regards products formed, were obtained by submitting gum arabic to the action of acids.

3. Pure furfural, when treated as under (2), yields 82—85 per cent. of humin substance, and traces of CO₂, CO, HCO₂H, &c.

4. Arabinose, on distillation with diluted phosphoric acid, yields, besides furfural (the authors have obtained up to 14 per cent.), carbon dioxide. The latter is continuously evolved during the whole time of distillation, and is formed in maximum amount (6 per cent.) when the operation is effected slowly and spread over a long period of time. In addition, a considerable percentage of humin substance is formed, and distinct proportions of volatile and fixed organic acids.—H. T. P.

Steffen's Sulphuration Process. Bauman. Centralbl. für die Zuckerind. der Welt, June, 1896.

The Steffen-Drucker process consists in passing a current of sulphurous acid gas through a saturated juice to the point of strongly acid reaction, and then filtering through powdered animal charcoal. In order to prevent inversion, the juices are kept, so long as they are acid, at a temperature of 30—40° C., and it is claimed that decoloration, boiling, and centrifugalising are alike favoured by the acidity of the juices. Experiments have been carried out on various

juices, and it is said that in general the use of sulphurous acid produces better coloured massecuites, but increases the ash, and does not alter the purity or non-sugar content of the juice. It is possible that the filtration of acid juices through charcoal eliminates a portion of the viscous matter, and so accounts for the easier boiling and slightly increased *rendement* as compared with the other processes. Any advantages, however, are counterbalanced by the cost, as the char, by reason of its acidity, cannot be revived or employed in the manufacture of manures. Amongst other drawbacks during evaporation, acid sulphite of calcium is deposited on the heating tubes, the calorific power being thereby diminished.—J. L. B.

Silica, On the Origin of, in Incrustations and Deposits in Beet-Sugar Works. The Solubility of Silicate of Lime and of Silica in Sugar Solutions. J. Weiβberg. Bull. Soc. Chim. de Paris, **15**, [18—19], 1097—1100.

THE incrustations in evaporating apparatus and deposits on filter-cloths of beet-sugar works show a greater quantity of silica than is accounted for by that contained in the diffusion juice, which showed on analysis only 10 mgrms. of SiO_2 per litre of juice at 7°B . The other possible sources are the limestone, the coke, and the masonry of the lime-kilns, which may introduce silica and silicate of lime into the juice from the milk of lime used in defecation.

The author finds that both calcium silicate and silica, prepared by precipitation and air-dried, are more soluble in solutions of sugar than in water, and that the solubility is increased by heating to boiling, by increasing the concentration, and by passing a current of carbonic acid gas. When the silica is previously calcined, somewhat less is dissolved.

A 10 per cent. solution of sugar, heated to boiling with an excess of calcium silicate, subjected to the action of carbonic acid gas for five minutes, and filtered hot, contained 0.0365 per cent. of CaSiO_3 .—L. J. de W.

PATENT.

Molasses, Syrup, or other Solution of Sugar, an Improved Method of Purifying, by Means of Animal Charcoal. C. F. Kastengren, Stockholm. Eng. Pat. 18,138, Aug. 15, 1896.

It is claimed that, by means of pressure, the purification of sugar solution with the help of animal charcoal may be effected in a shorter space of time, and with the employment of less animal charcoal, than by the ordinary filtration process. The sugar solution is heated with animal charcoal in a closed vessel to from 105° — 130° , or even higher, until the desired degree of purity is obtained. The purification may also be effected below 100° , and even as low as 50° , and in this case compressed air is made use of.—A. K. M.

Fermenting Yeast, Influence of Oxygen on. R. Rapp. Ber. 1896, 1893.

CHUDIAKOW (this Journal, 1895, 290) found that on passing a stream of oxygen through a fermenting sugar solution, the fermentation was gradually stopped, but that a stream of hydrogen did not affect the course of the fermentation. From these and other experiments Chudiakow deduces certain theoretical conclusions on the nature of fermentation.

The author has repeated these experiments, using pure yeasts, but with results contrary to those of Chudiakow; he, however, finds that a very vigorous stream of either hydrogen or oxygen will stop the fermentation, and this he considers to be a mechanical effect, as vigorous shaking has the same result.

The author concludes from his experiments that the presence of oxygen is necessary for the increase of the yeast, but not for the exercise of its fermenting power.

Beer, Japanese. C. Makel. Wochenschr. für Brau. **13** [41], 1036.

THE following is an analysis of the first sample of Japanese beer that has been seen in Germany. The bottle bears a label carrying in Japanese and Roman characters the inscription "Yebisu." Japan Beer Brewery Co., Meguro-mura, Tokyo, Japan. The beer was brewed by a German brewer:—

Specific gravity, 3.12° Balling; alcohol, 4.56 per cent.; extract, 5.23; maltose, 1.29; dextrin, 2.41; total acidity (as lactic acid), 0.161; albuminoids (nitrogen $\times 6.25$), 0.491; ash, 0.222; phosphoric acid, 0.051; glycerin, 0.126; original gravity, 13.98° Balling; apparent attenuation, 77.7 per cent.; real attenuation, 62.6 per cent.

The beer was of a clear gold-yellow colour, bright, with a fair amount of a white, flocculent sediment, rich in carbonic gas, holding a good head, and, allowing for the pasteurised flavour, of a clean, vinous, and pleasant taste. Microscopic examination showed the presence of albuminous matter only.

—J. G. W.

Vinegar, White-Wine. A. H. Allen. Analyst, 1896, **21**, 253.

WHITE-WINE vinegar was originally understood to mean a vinegar made from wine derived from white grapes, but of late years, distilled malt vinegar or simply diluted acetic acid has been very commonly sold in its place. Genuine white-wine vinegar always contains a notable quantity of acid potassium tartrate, which is not present in vinegar from other sources. Fourteen samples purchased from pharmacists in Midland towns were found to consist of either dilute

acetic acid or distilled malt vinegar. White-wine vinegar has the colour of sherry. It has a vinous aroma and peculiar flavour.—A. S.

PATENTS.

Waste Products [Spent Hops, Grains, &c.] from Breweries, Distilleries, Vineyards, &c.: Improved Methods of Utilising. J. Bradbury, Salford. Eng. Pat. 17,611, Sept. 21, 1895.

APPLIANCES are described for drying spent hops, grains, and other waste products, and thereby rendering them suitable for litter, and in some cases for cattle food, whilst in other cases the products are submitted to destructive distillation, the gas and acid distillate being collected, whilst the resulting vegetable charcoal is suitable for foundry use.—A. K. M.

Yeast, Impts. in the Manufacture of. [Peptonising Ground Grain with Spent Wash.] J. H. Folkerts, London. Eng. Pat. 18,296, Oct. 1, 1895.

A MASH is prepared from malted and unmalted grain, and, after saccharification of the starch, some spent distillers' slt is added, whereby the albuminoid matters are peptonised and rendered more suitable for yeast food. The rt is then separated, run into aerating vats, and fermentation started by the addition of yeast; the outcrop is separated in the ordinary way. The "grains" from the above operation are put into a vat with some yeast and moistened with sufficient spent wash or yeast washings to render fermentation possible. Afterwards the fermented wort (after removal of the yeast) is added, the whole distilled, and the residual spent wash is used for a future operation.—A. K. M.

Beer, Impts. in the Preparation or Treatment of. [Priming.] R. Free, Mistley, Essex. Eng. Pat. 20,130, Oct. 25, 1895.

A CONCENTRATED diastatic malt extract is prepared, diluted for use to a gravity of about 1.145 to 1.50, and added to the finished beer, generally in the proportion of about one to four pints to the barrel, according to the gravity of the beer and the purpose it is intended to serve. The malt extract may be used either alone or in conjunction with other priming materials; it imparts an improved flavour to the beer, and also brings the latter more rapidly into condition.—A. K. M.

Wort, A Process for the Aëration, Oxidation, and Oxygenation of. J. B. Grisez, Lachapelle-sous-Rougemont, France. Eng. Pat. 22,035, Nov. 19, 1895.

THE process consists in injecting filtered air into the hot wort as the latter enters the closed refrigerator, the wort being thus protected from atmospheric germs, whilst the aëration is more thorough than in the ordinary process.

—A. K. M.

XVIII.—FOODS; SANITATION, WATER PURIFICATION, & DISINFECTANTS.

(A.)—FOODS.

Cocoanut Butter and Cows' Butter, Comparative Digestibility of. Benrat and Jean. Comptes rend. **123**, [16], 587—590. (See also this Journal, 1896, 747.)

THE experiments were made on the human subject, each series lasting 5½ days, during which time 175.482 grms. of fat were supplied in the food, the remainder of the nutrient materials being arranged according to the albuminoid ratio most approved by physiologists. The total alimentary matter amounted to 15.770 kilos., representing 3.743 kilos. of dry matter, containing 80.233 grms. of nitrogen and 1534.293 grms. of carbon.

The actual amounts of fat digested were found to be: cocoanut butter, 463.03 grms.; cows' butter, 455.65 grms., or respectively 98 per cent. and 95.8 per cent. of the total fat supplied, thus demonstrating the superior digestibility of the former, and as the cocoanut butter employed had been pressed, and deprived of the greater portion of its soluble volatile glycerides, it is evident that the high ratio of digestibility of cows' butter is not due to its content of these, as formerly supposed.—C. S.

PATENT.

Protection of Sterilised Liquids. F. T. Bond, M.D., Gloucester. Eng. Pat. 20,328, Oct. 29, 1895.

THE liquid is sterilised by heat in the vessel in which it is to be stored, round the neck of which is a rim.

Whilst still hot a tightly fitting india-rubber capsule is slipped on over the rim. On cooling, the unsupported part of the capsule is forced inwards by atmospheric pressure, and will remain in this position so long as the contents of the vessel are sterile.

Should fermentation take place the gases given off will force the capsule outwards.—R. B. P.

(B.)—SANITATION; WATER PURIFICATION.

Dangerous Gases [Chemical Works], Rules suggested by the Chemical Trade Journal for dealing with. Chem. Trade J. 1896, **19**, 250.

General Regulations.—No person must enter any boiler or tank which has been recently used for the storage of any poisonous liquid or gas, or enter any dangerous workings, drain, sewer, culvert, gas purifier, flue, vitriol chamber, or tower (whether closed or open), except under the following conditions:—(1.) A respirator, properly charged and in good condition, must be worn. If the atmosphere is wholly irrespirable, a safety-pipe and face-piece supplied with air or oxygen must be substituted. (2.) The person entering must be efficiently secured round the waist by a rope, the opposite end of which must be securely fastened to the ground at the surface, or at the top of the tower or flue, &c. (3.) A man must be in attendance and ready to render assistance if necessary. For underground work and in difficult positions, two men must be in attendance.

When a man is gassed, remove as quickly as possible into the open air, and place in a well-ventilated position and keep as warm as possible. In bad cases use the oxygen bottle and lung exercise simultaneously, from the outset.

Use of Oxygen Bottle.—If conscious, let the oxygen flow in a gentle stream through the glass tube which is placed in the mouth, and let it be breathed until relief is obtained. If unconscious, place the oxygen delivery tube in one corner of the mouth, and close the lips round it. Keep the oxygen flowing in a gentle, continuous stream, alternately closing and opening the nostrils to inflate and deflate the lungs. (Gently pressing the chest when the nostrils are open assists the deflation.) If the teeth are set, close the lips, insert the oxygen tube in one nostril, and alternately close and open the other in the manner just described. Complete inflation of the lungs is indicated by the blowing out of the cheeks. Carefully avoid too great a pressure in the lungs.

Artificial Respiration.—This is not often necessary, but if the oxygen does not act within a reasonable time, use the following additional help to respiration:—Lay the body at full length, face upwards, slightly raising the shoulders, and

letting the head fall well back. Loosen the clothing round the neck and chest. Grasp the arms above the wrist and steadily draw them straight out above the head, holding them there for two seconds. Then turn the arms down, bending the elbows, and at the same time pressing them firmly against the sides of the chest, and hold them in that position for two seconds. Continue this treatment about 15 times a minute for 20 minutes without cessation, or until consciousness is restored.

The following gases, according to the frequency of their occurrence, are roughly arranged in order of danger:—

Nitrous and Nitric Acid Fumes.—Very insidious in their action. Can be inhaled at first without great inconvenience, but sooner or later (sometimes after several hours), they react acutely, producing symptoms that need very prompt treatment. When there is any suspicion of gassing, remedial measures should always be adopted, whether there is any distress or not, and careful watching is advisable during the ensuing 12 hours. The gases are met with in Gay-Lussac towers and vitriol chambers during repacking or cleaning, and also in the manufacture of nitrate of iron and nitric acid, and all breakages of vessels containing this acid. In the case of Gay-Lussac towers, the bottom or top of the tower should be temporarily connected to the flue, to create and maintain a steady draught away from those engaged in unpacking. Vitriol chambers should be worked weak for some time, and well steamed and ventilated before opening.

Sulphuretted Hydrogen and Chlorine.—Sulphuretted hydrogen is one of the most dangerous gases, insensibility resulting very suddenly with even small quantities. Oxygen is the best restorative. The gas occurs in gas liquor-storage wells, gas purifiers, sulphate stills and saturators, and in sewers (in conjunction with carbon dioxide). In the case of an unexpectedly copious outburst, "the absorbing respirator" acts well. Owing to the smell and colour of chlorine, bad cases with this gas can only be due to gross carelessness. The instantaneous and continued use of all possible remedies is recommended. The "gas mixture" should be administered at once, and can be followed with oxygen whiffs, whiskey, or hot tea, with a view of inducing free perspiration. Chlorine occurs about bleaching powder chambers, manganese stills, and Deacon and other chlorine plant.

Carbonic Oxide and Carbon Dioxide (after damp and choke damp).—The former is the more dangerous, being a direct poison. It occurs in colliery workings after explosions, gas producers, blast furnace gases, and in the manufacture of calcium carbide. In cases of gassing with this, and also with carbon dioxide, longer treatment is necessary, as the lungs have to be cleared by displacement, and the use of oxygen may be supplemented by the lung exercise. Carbon dioxide occurs in the same places as sulphuretted hydrogen and also in the fermentation rooms in breweries, in coal pits, old workings, disused wells, &c.

Hydrocyanic Acid Gas and Arseniuretted Hydrogen; Hydrochloric Acid Gas and Sulphur Dioxide.—The first two are not of very frequent occurrence. Oxygen should always be kept handy, where their formation and escape are possible. With hydrochloric acid and sulphur dioxide, virtually no accidents have been recorded.—A. S.

Accidents and Dangers in Dye, Print, and Bleach Works.
Albrecht. *Leipziger Färber Zeit.* 45, [10], 439.

A discussion of the hygienic conditions of dye, print, and bleach works, and the dangers as to accidents and poisoning to which the workpeople are exposed, with suggestions for their prevention.—I. S.

(C.)—DISINFECTANTS.

PATENT.

Disinfectants and Antiseptic Compounds, Impts. in the Manufacture of. C. C. Whitaker, East Dulwich, London.
Eng. Pat. 22364, Nov. 23, 1895.

The patentee mixes pyridine bases or their salts with sodium carbolate or cresylate in aqueous solution, saturates the mixture with carbolic or cresylic acid, and adds to the aqueous portion, which he separates, from 0.5 to 1 per cent. of β -naphthol. This disinfectant, which is to be employed

as an insecticide or a sheep dip, can be obtained in a solid form by mixing from 5—20 per cent. of the solution with powdered chalk, gypsum, or other suitable material. The name "Deodo" is to be applied both to the solid and liquid material.—T. A. L.

XIX.—PAPER, PASTEBOARD, Etc.

Wood Pulp in Paper, Some Methods for the Detection and Estimation of. Wood Pulp, 1, [3], 1896, 61.

See under XXIII., page 833.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES AND EXTRACTS.

Hydrogen Peroxide [Keeping Powers]. Vulpinus. *Chem. Zeit.* 1896, 20, 795.

Portions of hydrogen peroxide solution of 3.27 per cent. strength, containing a little free sulphuric acid, were kept for 120 days under different conditions. In all cases the strength was reduced. The percentage in the sample kept in the dark in a full bottle was reduced to 2.71; in a half-filled bottle in the dark to 2.62; and in the light to 2.54; all these bottles having the inner surface covered with a layer of paraffin to obviate the effect of the glass surface. In bottles not paraffined, but filled with broken glass, the percentage had become, in a full bottle in the dark, 2.67; in the light, 2.5; in a half-filled bottle in the dark, 2.5; and in the light, 2.45. By no precautions could the decomposition of these solutions be prevented, but in no case did the percentage fall so low as the minimum of 2.15 allowed by the German Pharmacopœia.—A. C. W.

Mercury, Action of Ferric Chloride upon. P. Süß.
Pharm. Central-Bl. 1896, 17, 547.

LAURENZ had proposed to prepare mercury for use in mercurial ointment by shaking the metal with ferric chloride solution; but as this gives rise to a production of calomel, the method does not work satisfactorily. It is, however, suggested as very possible to utilise the reaction for the production of pure calomel, with the aid of a centrifugal machine and a gauze sieve.—W. G. M.

Alkaloids of Corydalis Cava. H. Ziegenbein. *Chem. Central-Blatt.* 1896, 2, 792.

FROM 10 kilos. of tubers were obtained, by the method of Freund and Josephi, 57 grms. of corydaline, 41 grms. of bulbocapnine, 6 grms. corycavine, and 4 grms. corybullbine. Corytuberine and corydine (Dobbie and Laufer) were not found. On account of the different statements made as to the properties of these alkaloids, very pure preparations were studied.

Corydaline, $C_{22}H_{27}NO_4$, easily soluble in warm alcohol and chloroform, when crystallised from alcohol, forms large transparent prismatic crystals of melting point 134° — 135° . The alcoholic solution on heating, acquires a yellow colour; nevertheless, from the yellow solution colorless crystals of the base separate. Both the crystals and alcoholic solution are coloured yellow by light. Alkalis and alkaline carbonates precipitate the alkaloid from aqueous solution of its salts, and the precipitate is not soluble in excess of either. The hydrochloride could not be obtained crystalline, the hydrobromide $C_{22}H_{27}NO_4 \cdot HBr$ and hydriodide crystallise from water in strongly refractive rhombic crystals, the latter turning yellow in the air. The nitrate, $C_{22}H_{27}NO_4 \cdot HNO_3$, crystallises from alcohol in shining tables of melting point 198° , soluble with difficulty in hot water.

Iodine only reacts completely with corydaline in alcoholic solution, on heating in a closed vessel on the water-bath. After removal of iodine in excess and that combined as periodide, by addition of potassium iodide, sodium bicarbonate, and finally thiosulphate, dehydrocorydaline hydriodide, $C_{20}H_{23}NO_4 \cdot HI + 2H_2O$, crystallises out of the solution. This salt recrystallised from alcohol, forms small yellow needles unaffected by light, very soluble in hot

alcohol, slightly so in cold alcohol, and very little in hot water. Dehydrocorydaline hydriodide boiled with acetone and water, on addition of excess of caustic soda, gives an acetone compound, which, by the action of hydrochloric acid, forms the hydrochloride. Chloroformdehydrocorydaline, $C_{22}H_{23}NO_4 \cdot CHCl_3$, obtained by warming the foregoing hydriodide with water, chloroform and caustic soda, does not lose weight at 100°.

Bulbocapnine, $C_{22}H_{23}NO_4$, by treatment with iodine, forms a black periodide, which does not decompose as does the corresponding corydaline compound. Heated with methyl-iodide under pressure, the compound $C_{22}H_{23}NO_4 \cdot CHI_3$ was formed, of melting point 235–240° (Frennd gives 257°).

Corycavine, $C_{22}H_{23}NO_4$, rhombic tables, very sensitive to the action of light, melting point 215°–216°, precipitated by alkalis and alkaline carbonates, and insoluble in excess of the reagent, much less soluble in alcohol than corydaline. $C_{22}H_{23}NO_4 \cdot HCl$ crystallises from hot water in thick colourless needles uniting to rosettes.

Corybulbine, $C_{22}H_{23}NO_4$, had the properties described by Dobbie and Lauder, but the melting point 238°–239° C., $C_{22}H_{23}NO_4 \cdot HCl$, yellow prismatic needles, soluble with difficulty in hot water, more readily in presence of hydrochloric acid. The base reacts with iodine to produce $C_{22}H_{23}NO_4 \cdot HI$, lemon-yellow needles.

Behaviour of the bases towards different reagents:—

	Corydaline.	Dehydrocorydaline.	Bulbocapnine.	Corycavine.	Corybulbine.
Conc. H_2SO_4	After long time red and violet.	..	Orange, after 10 minutes violet.	Dirty green, brown, violet.	..
Conc. H_2SO_4 at 100	Yellow	Yellow	Violet	Dark green	..
Conc. HNO_3	Yellow	Yellow	Reddish-brown	Red	Yellow
Erhmann's reagent	Yellow, green, violet.	Yellow, green, violet.	Blue, bluish-violet	Dirty green	Yellow
Froehde's reagent.....	Yellow, pale green, fine blue.	Yellow, blue	Dark blue	Dark green	Red, brown, green
Sulpho-vanadic acid.....	Yellow, green, blue.	Yellow, green, blue.	Bright blue, blue	Dark green	Brown, green

— A. C. W.

Corydalis Alkaloids. E. Schmidt. Chem. Centralblatt. 1896, 2, 792.

DEHYDROCORYDALINE is obtained by the action of iodine on corydaline—

the same reaction is given by canadine and hydroberberine, and by corybulbine $C_{22}H_{23}NO_4$ only, of the remaining corydalis alkaloids. Dehydrocorydaline, $C_{22}H_{23}NO_3$, like berberine, forms compounds with acetone, chloroform, and hydrogen polysulphide, is reduced by nascent hydrogen to a colourless base of the same composition and melting point as corydaline, but forms a different double salt with gold chloride. Bulbocapnine and corycavine were also isolated from corydalis tubers.—A. C. W.

Arginine. M. Quiroga. J. Pharm. Chim. 1896, 16, 293.

This alkaloid is contained in the different parts of a species of laurel, called by the natives *vivaró-mi*, growing in the country to the east of the Argentine, and the west of Brazil. Arginine is extracted from the dried and powdered material by ordinary methods. It forms prismatic crystals, unaltered in the air, with a bitter taste, soluble in chloroform and benzene, and slightly soluble in ether, petroleum spirit, and water. The aqueous solution slightly acidified with hydrochloric acid, gave the following reactions:—With bromine vapour, a white precipitate, soluble in water; with ammonia, caustic soda or potash, sodium carbonate, and bicarbonate, a white precipitate, soluble in excess (the precipitate produced by caustic potash is turned a reddish-brown by hydrochloric acid); with fuming nitric acid, a carmine red coloration; with ferric chloride, a blood-red coloration; with gold chloride, a yellow precipitate, which is then reduced, giving violet, carmine, blue, and black colorations; with platinum chloride, a crystalline precipitate; with solid potassium bichromate, an intense carmine is produced, destroyed by sulphuric acid; with potassium ferrocyanide, a light blue colour, destroyed by excess of the reagent; with Millon's reagent, a red coloration, changing to carmine violet. With Fehling's solution no change occurs.

The bark and cambium contain 1.5 to 1.6, the wood and leaves 0.042–0.05 per cent. of the alkaloid. It may be determined by Meyer's reagent, 1 c.c. of which corresponds to 0.0135 grm. of arginine.

Arginine is used successfully to "combat certain diseases of microbial origin." It has given satisfactory results as a tonic.—A. C. W.

Taxine, Extraction and Purification of. Vreven. Pharm. J. 1896, 4, 215. Bull. Gén. de Thérap. Sect. Pharm. 1, 261. Pharm. J. 4, 1896, 215.

THE author extracted this alkaloid from yew leaves as follows:—Fresh yew leaves, cut up small, are extracted with water acidulated with tartaric acid, the extract evaporated on a water bath to a small bulk, mixed with sufficient sand to form a paste, and then exhausted with a mixture of equal volumes of water and alcohol in successive portions. This extract is filtered, evaporated, rendered alkaline with ammonia, and shaken out with benzene. The solvent separates fairly well from the emulsion formed by the ammonia, on the addition of a little alcohol. The benzene extract is partially distilled, and on cooling, throws down a trace of precipitate, apparently alkaloidal, but not taxine. This is filtered off, and the taxine shaken out from the residual benzene with dilute hydrochloric acid. The acid solution gives with ammonia a plentiful precipitate, which is taken up with ether. The ethereal solution on evaporation leaves the impure taxine as a hard yellowish amorphous mass, giving a red coloration with sulphuric acid, and a slight blue tint with nitric acid, passing on to blue on contact with fuming hydrochloric acid. The alkaloid is further purified by redissolving in hydrochloric acid and precipitating with an excess of ammonia, being allowed to stand in contact with the latter for 12 hours. The taxine subsides, leaving a greenish liquid, which is decanted and filtered. The alkaloid remaining behind, does not give a green coloration on again macerating with ammonia; it still gives the characteristic reaction with sulphuric acid, but no longer with nitric or hydrochloric acid.

So far as colour and alkaloidal reactions would indicate, it would seem that the yew leaves contain more than one alkaloid.—A. S.

Essential Oils. Dnyk. J. Pharm. Chim. 1896, 4, 359.

THIS is a continuation of the article abstracted in this Journal, 1896, 739–740.

Lemon-grass Oil is composed almost entirely of citral. To separate this constituent, shake with concentrated bisulphite of soda solution, press the crystalline mass, and wash with ether to remove geraniol; decompose with dilute sulphuric acid, separate the citral, wash and dry.

Artificial Essence of Violets (Ionone).—The odour of the violet is very similar to that of iris root, the odoriferous principle of which Haarmann and Reimer have shown to be the ketone, $C_{15}H_{26}O$, which, by the action of dehydrating agents, is converted into the hydrocarbon $C_{15}H_{24}$. Tiemann

and Krüger have obtained an isomer of irone, ionone, which has the odour of the violet. (See this Journal, 1894, 272, and 1895, 827.)

Geranium Oil is the name by which essences derived from very different sources, characterised by the presence of geraniol, are known. True geranium oil has a density of 0.894, and a rotation of -8.12 to 9.55 . Palmarosa oil has the same density and a rotation of -1.55 . Geraniol is non-rotatory, and of density 0.8835. After acetylation its index of saponification is 2.872 (Schimmel). It may be extracted from these essential oils by mixing them with powdered anhydrous calcium chloride, crushing the resulting solid compound, washing with ether, and decomposing by water. Réniol is another alcohol always found together with geraniol in geranium oils, and the mixture of the two alcohols constitutes the rhodinol of Barbier and Bouveault (this Journal, 1896, 292, 373, 469). Geraniol is also found in essence of roses. Schimmel's artificial essence of roses is obtained by distilling 1 kilo. of geraniol over 500 kilos. of rose petals.

Otto of Roses.—The value of this oil is now fixed by its content of stearoptene; but this substance is odourless, and so cannot increase the quality of the essence. The statement of certain authors that the stearoptene will change by gentle oxidation into the eleoptene cannot be practically confirmed. Pure Turkish otto contains 9–13 per cent. of stearoptene, and melts at 16° – 21° . German otto contains 26 per cent., and melts at 27° . Other pure samples, and especially French, have a lower melting point; thus the melting point is no criterion of purity. A relatively high melting point might indicate adulteration with paraffin, spermaceti, &c., and a low melting point with other essential oils, such as geranium oil. The solid otto of roses should be spangled with crystalline plates, which, on melting by the heat of the hand, should rise to the surface of the liquid. The stearoptene obtained by dissolving in chloroform, adding alcohol of 75 per cent. strength, washing and drying, should have a constant melting point. The addition of strong sulphuric acid to five drops of otto produces a thick reddish-brown mass, which, in the absence of essences of geranium, &c., will not evolve any acid tarry odours. The pure essence has a density of 0.865–0.880 at 20° , and contains the same mixture of geraniol and réniol (roseol) which has been called rhodinol.—A. C. W.

Eucalyptus Kinoo, Aromadendrin or Aromadendric Acid from the Turbid Group of. H. G. Smith. Journ. Royal Society, N.S. Wales, 1896, 135.

In a former investigation the author and J. H. Maiden found that the turbidity produced on cooling a solution of the kino of *Eucalyptus hemiphloia* in hot water was due to the presence of two bodies, to which the names eudesmin and aromadendrin were given. In the kino of *E. calopylla* the latter body occurs free from eudesmin. To extract aromadendrin, the finely-powdered kino is mixed with a little water, and extracted by ether, and the residue, after evaporation of the solvent, recrystallised from absolute alcohol.

Aromadendrin is readily soluble in ether, acetic ether, alcohol, and amyl alcohol; almost insoluble in chloroform; and quite insoluble in benzene and petroleum spirit. From any of the solvents mentioned it crystallises in acicular radiating tufts, it is soluble in hot water and in 2,777 parts of cold water. Analysis indicates the formula $C_{25}H_{36}O_{12}$ for the anhydrous substance; it crystallises with three molecules of water, two of which are lost at 100° and the third between 100° and 120° C.

The following table shows the difference between aromadendrin and eudesmin:—

	Eudesmin.	Aromadendrin.
H_2SO_4 , conc.	Dark solution, purple after half an hour.	Yellow solution, turning dark, and fading. Orange on heating.
HNO_3 , conc. or fuming.	Yellow solution, from which yellow crystals separate.	Fine crimson solution.
KOH	Little change	Fine yellow solution, colour persistent.

	Eudesmin.	Aromadendrin.
Glacial acetic acid	Dissolves. On addition of little water solution becomes turbid and then crystallises.	Dissolves. No turbidity on addition of water. Tufts of crystals on standing.
Melting point ...	30° C. either on surface of mercury or in glass tube.	216° C. (uncorr.) on surface of mercury. Determination in tube unsatisfactory.
Heated between watch glasses.	Melts at low temperature to clear liquid. Chars very slightly.	Melts at high temperature, and darkens at once. Chars quickly.
Chloroform	Readily soluble	Almost insoluble.
Formula	$C_{26}H_{36}O_{12}$	$C_{25}H_{36}O_{12}$ after heating to 120° . $C_{15}H_{26}O_{12} + 3H_2O$ when air-dried.

The strong solution of aromadendrin in hot water reddens litmus, gives a dense yellow precipitate with lead acetate, which contains 45 per cent. PbO or 2 atoms of lead in the molecule; with copper sulphate a light greenish precipitate is formed. Gold chloride, silver nitrate, and Fehling's solution are readily reduced; gelatin gives no precipitate; ferric chloride a purplish brown colour; alkalis a yellow to orange coloration. When boiled with copper sulphate or potassium bichromate and cotton, no colour is imparted to the latter. Aromadendrin, though similar to catechol in many respects, yet differs from it in others. Heated in glycerine it does not form pyrocatechol, but a yellow resinous substance, which can be extracted by ether, and has great tinctorial powers.—A. C. W.

Cacti, Chemical Characteristics of. Heffter. Chem. Zeit. 1896, 20, [81], 796.

Anhalonium Williamsii.—The fresh plant contains 0.9 per cent. of the alkaloid pellotine, $C_{11}H_{12}N(OCH_3)_2.OH$, a tertiary base. Pellotine, its salts, and double salts crystallise well; its action is hypnotic. Traces of a volatile alkaloid, also malic acid, and quercite, have been found in the plant (this Journal, 1895, 384; 1896, 554).

Anhalonium Lecinii.—This is botanically identical with the last species, but not chemically. It contains 0.5–0.6 per cent. of anhalonine, $C_{12}H_{13}NO_3$, which crystallises well, is levo-rotatory, and is also a hypnotic. It contains one methoxyl group. The plant contains in addition mescaline, $C_{11}H_{17}NO_3$, anhalonidine, $C_{12}H_{17}NO_3$, lophophorine $C_{13}H_{17}NO_3$, malic acid, and much potassium chloride. Lophophorine is a powerful convulsant.

Anhalonium fissuratum contains 0.02 per cent. of anhaline, $C_{10}H_{17}NO$, which gives a green coloration with nitric acid.

Anhalonium prismaticum contains a little of a very poisonous alkaloid not yet investigated.

A. Jourdanianum, a very powerful alkaloid, causing convulsions. Many other cacti have been shown to contain traces of alkaloids.—A. C. W.

PATENTS.

Hexamethylenetetramine, Manufacture of a Compound of Salicylic Acid and. O. Imray, London. From "The Farbwerke vormals Meister, Lucius and Brüning," Höchst a. M., Germany. Eng. Pat. 22,181, Nov. 25, 1895.

THE two substances mentioned in the title, when boiled together in molecular proportions in benzene, combine to form a new compound: 1.38 kilos. of salicylic acid, and 1.4 kilos. of hexamethylenetetramine are boiled with sufficient benzene to obtain a clear solution. The new compound separates out on cooling, and is filter-pressed and dried. It dissolves easily in water or alcohol, but is less soluble in ether, petroleum ether, or benzene, and melts at 95° C.—T. A. L.

Iodoform, New and Useful Bodies derived from. A. Kiehngrün, Bonn, Germany. Eng. Pat. 21,203, Nov. 8, 1895.

IODOFORM combines with hexamethylenetetramine and its alkylaloid derivatives, forming additive compounds, which easily decompose, liberating iodoform. To a solution of 14 grms. of hexamethylenetetramine in absolute alcohol is added 39.4 grms. of iodoform and the mixture is heated for a short time on the water-bath. The fine white powder of the compound, $C_6H_{12}N_4 \cdot CHI_3$ (iodoformin), separates out, being insoluble in water, ether, or alcohol. It melts at 178° C. In place of hexamethylene-amine, 23.4 grms. of phenolhexamethylene-amine may be taken, when the same compound is formed. If, however, 29.6 grms. of ethyl iodide-hexamethylenetetramine, and 39.4 grms. of iodoform be heated in an alcoholic solution for a short time, crystals are deposited, which consist of iodoformethylhexamethylene-iodide (iodoformal). They melt at 128° C., are insoluble in water, but soluble in hot alcohol, and by prolonged heating of this latter solution another compound is produced, melting at 172° C. Other compounds which have been obtained are iodoform-methylhexamethylene-amine iodide, light yellow needles, easily soluble in alcohol, melting at 179° C., and iodoform-methylene-iodidehexamethylene-amine, small yellow needles, m.p. 174° C. Similarly, bromethylhexamethylene-amine, which melts at 155° C., forms a new compound with iodoform, easily soluble in alcohol, crystallising in light yellow prisms, and melting at 111° C.—T. A. L.

Imide of Orthosulphobenzoic Acid [Saccharin], Impts. in the Manufacture or Preparation of the. G. W. Johnson, London. From the "Chemische Fabrik vorm. Goldenberg, Geromont, and Co.," Winkel-on-the-Rhine, Germany. Eng. Pat. 1956, Jan. 28, 1896.

By the action of concentrated caustic soda on *p*-nitrotoluene *o*-sulphonic acid a brownish-red condensation product is obtained, which, on reduction with zinc-dust, yields diamido-stilbenedisulphonic acid (Bender and Schultz, Ber. 19, 3236; this Journal, 1887, 817). From this substance the patentee obtains saccharin by the following process:—The product is first of all converted into the dihydrazine compound and 4 kilos. of the dihydrazidostilbene-*o*-disulphonic acid (short brownish-yellow needles almost insoluble in water), and 5 kilos. of crystallised copper sulphate are boiled together in about 50 litres of water until the evolution of nitrogen has ceased. The resulting stilbenedisulphonic acid, $HO_3C_6H_4 \cdot C_6H_4 \cdot SO_3H$, is converted into the soluble lime salt, filtered from calcium sulphate, and the solution evaporated to about 10 litres, when it is converted into the sodium salt by treatment with 1.1 kilos. of sodium carbonate. The sodium salt obtained by evaporating the filtered solution to dryness, is stirred to a thin paste with phosphorus oxychloride, to which 4.2 kilos. of finely-powdered phosphorus pentachloride are gradually added. After distilling off the phosphorus oxychloride a pulverulent mass of sodium chloride and stilbene-*o*-disulphochloride remains. This mixture is stirred into 6 kilos. of 25 per cent. ammonia, when stilbene-*o*-disulphonamide is produced, which, on distilling off the excess of ammonia, crystallises out in small needles. After

washing, to remove salt and ammonium chloride, the sulphonamide is dissolved in 22.4 kilos. of a cold 5 per cent. solution of potash, and oxidised with 4.3 kilos. of potassium permanganate in 70 litres of water, the whole being heated to 40°–60° C. until the clear liquor is of a yellow colour. The solution is then filtered, neutralised with hydrochloric acid, evaporated to about 5 litres, again filtered and treated with concentrated hydrochloric acid, when the imide of *o*-sulphobenzoic acid (Saccharine) separates out, and may be purified by recrystallisation.

—T. A. L.

Ozone Solutions, Impts. in the Production or Manufacture of. A. Spranger, Berlin, Germany. Eng. Pat. 18,924, Aug. 27, 1896.

THE process consists in passing ozone into essential oils, especially oil of citron, which may be used pure or else diluted with alcohol, in order to obtain permanent ozone solutions of definite strengths. For medicinal purposes a 60 per cent. alcohol is used, containing 0.5 per cent. of citron oil. Ozone is passed into this solution until saturated, and for use 40 drops are recommended to be taken in water as an anti-septic remedy.—T. A. L.

XXI.—PHOTOGRAPHY.

Developer, Photographic, Formaldehyde in. A. Helheim. Phot. Arch. 1896, 37, 203.

THE author has introduced formaldehyde into the alkaline pyrogallol developer, with the object of developing the image and hardening the film by the same solution. He finds that development is hastened, but the pyrogallol solution is rapidly spoiled by its use, depositing a brownish-yellow veil on the plate. A free use of potassium bromide prevents the latter action, but it is better to immerse the plate in a bath of 2 per cent. formaldehyde solution prior to the ordinary development than to mix the two solutions.

—W. G. M.

PATENT.

Photographic Printing Paper, Impts. in [Tinting first, Albuminising after]. G. Koppmann, Hamburg. Eng. Pat. 22,632, Nov. 27, 1895.

TINTED albuminised papers are usually prepared by coating with an albumin solution, to which some blue or rose coloured "aniline" dye has been added. As these tints are apt to be fugitive, the inventor prefers staining the original paper as a separate operation, whereby it becomes possible to use a permanent colour, such as cobalt blue.

—F. H. L.

XXII.—EXPLOSIVES, MATCHES, Etc.

Peracide of Lead, Improved Method of Manufacture of. H. M. Warren. Chem. News, 1896, 74, 144.

See under XI. B., page 816.

PATENTS.

Nitrocellulose and Cellulose Compounds, Impts. in or relating to, and Articles Manufactured therefrom. U. Marga, Brussels, Belgium. Eng. Pat. 21,470, Nov. 12, 1895.

THE new material called "cellulodine," described in this patent, consists of a mixture of nitrocellulose (soluble in ether-alcohol), and cellulose, which is treated with ether-alcohol, and the mass after kneading can be cast or worked into any desired form. The proportion of cellulose used modifies the toughness of the product. Flour, &c., may be used instead of cellulose, and the nature of the product may be varied by the addition of castor-oil or other greasy matter. Cellulodine made with fine, well-dried wood powder is stated to be well suited for the manufacture of bullets (for practice or drill cartridge), adapted to fall to pieces under the action of the gases produced by the combustion of the powder.—W. M.

Explosive, A New. H. Boyd, Birmingham. Eng. Pat. 10,403, May 15, 1896.

This is a patent for an explosive composed of the following ingredients in about these proportions:—Potassium nitrate 7 parts, commercial sulphur 3, Irish bog-ore 2, barium nitrate 2, picric acid 1, wood-dust 1. The Irish bog-ore is used to absorb the fumes resulting from the firing of explosives.—W. M.

Explosive, An Improved, or Blasting Composition. B. Willcox, London. From Aetien Gesellschaft Dynamit Nobel, Vienna, Austria. Eng. Pat. 18,078, Aug. 14, 1896.

A BLASTING explosive is formed by mixing ammonium nitrate, potassium permanganate, and 1—3 per cent. of nitroglycerin. This mixture is stated to be very safe in the presence of fire-damp or coal-dust, on account of its low temperature of explosion.—W. M.

XXIII.—ANALYTICAL CHEMISTRY.

APPARATUS, ETC.

Pyrometer, Le Chatelier-Heraeus, Use of, in Iron Works. H. Wedding. Stahl u. Eisen, 1896, 16, 663.

OF the two pyrometers in practical use, the Siemens (resistance) and the Le Chatelier instruments, only the latter may be considered reliable according to the work of Holborn and Wien. As applied to the determination of the temperature of the blast, of the gases, or of the furnace itself, the customary porcelain or fire-clay protecting-tubes are not well adapted to rapid heating; and the author therefore recommends that the wires should be threaded through fragments of pipe-stems, whilst the junction itself is provided with a cap of asbestos cardboard. The pipe-stems are firmly bound round with asbestos cord, so that any evil effects of fracture may be guarded against. Such an arrangement may be applied to determining the temperatures of reheating furnaces or of iron-nickel alloys before and after rolling. But for use with molten metals or slags, the author fills the bulb of a porcelain flask with tungsten and ignited charcoal, closes the bulb with an asbestos stopper, and introduces the thermal couple into the neck of the flask. The whole is surrounded with asbestos, and covered with a cap of the same, so that no harm may result from the fracture of the tube. This arrangement will then float upright in the molten material. —W. G. M.

Hydrometer with Correction Scale. [Sugar Solutions.] Volquartz. Zeits. des Ver. Rübenzuckerind. 1896, 46, 392.

This hydrometer has a thermometer formed inside, which, instead of marking degrees of temperature, shows the correction to be made in the reading of the hydrometer.

—L. J. de W.

Glue, An Apparatus for Testing. R. Wischin. Chem. Zeit. 1896, 20, 827.

DOEBT having been thrown by Kissling (this Journal, 1896, 729) on the usefulness of an apparatus invented by the author, the latter writes that his method for testing glue has not been strictly adhered to, and thus accounts for the difficulties met with by Kissling, who asserts that it is impossible to tell whether the metal disc of the balance has already sunk into the glue or is only sinking. The observation is not to be taken during the sinking of the metal plate, but at the moment when the glue begins to split or tear, and this tearing is so evident that it cannot be mistaken. A glue to be tested is made up into a jelly consisting of 1 part of the glue to 3 parts of water, or 1 part of glue to 5 parts of water, the latter consistency giving the better results.

The method is useful for testing the glue used for closing up the interstices in petroleum barrels.

A glue solution was prepared of this degree of dilution, because the author had convinced himself, that glue solutions of such dilution as to form no jelly at 12° C., are

useless for protecting the interiors of petroleum barrels. Such glues would give negative results with the testing apparatus.—W. P. S.

Blowpipe Analysis, some Extensions of the Plaster of Paris Method. W. W. Andrews. J. Amer. Chem. Soc. 18, 10, 849—869.

THIS research indicates an extension of the practical art of blowpipe analysis by aid of plaster of Paris tablets in place of charcoal. Reactions are given for the following elements, both separately and when in presence of those which commonly accompany them in nature, viz., Cu, Ag, Au, Zn, Cd, Hg, Tl, C, Si, Ge, Sn, Pb, N, V, As, Sb, Bi, S, Se, Te, Cr, Mo, W, U, F, Mn, Cl, Br, I, Co, Ni, Pd, Os, Ir, Pt.

The reactions described have been obtained from a large number of the compounds of each of the above elements, except in the cases of Os, In, and Ir.—V. C.

INORGANIC CHEMISTRY.—QUALITATIVE.

Nitrites, Detection of, in Presence of Sulphites; some Colour Reactions of Brucine. P. Picard. Comptes rend. 123, [16], 590—592.

IN the presence of nitrites, hydrochloric acid colours brucine vermilion-red to clear yellow, the reaction being sufficiently delicate to reveal 1 part of "nitrous nitrogen" in 640,000 parts of water. Since the presence of sulphites decreases the delicacy of the Picini, Tromsdorff and Griess' methods of determining nitrites, the author proposes to employ instead, the above-named colour tests in cases—such as the drainage waters from land treated with sulphatic manures—where these two classes of compounds are associated.

The best method of detecting sulphur dioxide in such cases is by its odour, to which end it is liberated by the action of a strong acid, the evolution of hydrogen sulphide being prevented by precipitation with lead sulphate and filtration. If SO₂ be present then the nitrite test is applied, in the manner prescribed for the nitrate test. (See following abstract).

Chlorine and the hypochlorites do not colour brucine, but will give a vermilion-red with certain brucine salts, i.e., nitrate, chloride, acetate, and sulphate, the latter giving the most decided results.—C. S.

INORGANIC CHEMISTRY.—QUANTITATIVE.

Nitrates in Vegetable Products, Rapid Estimation of. P. Picard. Comptes rend. 121, [22], 758—760.

TWO to 4 grms. of the organic matter, previously dried at 100° C., and pulverised, are rapidly heated nearly to boiling point, in 20 c.c. of water, in a flask with a long narrow neck, which is thereupon closed and set in a warm place for a quarter of an hour to dissolve the nitrates present, solution being assisted by occasional agitation. After cooling, the solution is filtered through animal charcoal, and collected in a small flask, the funnel being covered with a glass plate. The small flask is kept closed air-tight until the time of titration. Two c.c. of the liquid being transferred to a 50—60 c.c. test glass, one drop is removed by means of a glass rod and placed on a flat plate of white porcelain. To this is added a single drop of monohydrated sulphuric acid, and when thoroughly mixed together a piece of crystallised brucine, the size of a pin head, is dropped into the mixture. In presence of nitrates an intense red coloration develops immediately around the brucine and quickly spreads concentrically. The liquid in the glass is then diluted by successive additions of 2 c.c. of distilled water until, in a repetition of the test, the coloration no longer appears at the end of five minutes. The entire test is afterwards repeated with greater exactness by reducing the rate of dilution to fractions of a c.c. of water towards the end. At this point the liquid contains 0.0207 gm. of "nitric nitrogen" per litre, corresponding to 0.08 gm. of nitric acid, or 0.15 gm. of potassium nitrate, and the method is capable of detecting 1 part of nitrogen in 50,000 parts of water. When nitrites are present (these also giving a coloration with brucine) their amount is estimated

by one of the ordinary methods, and in the final test with bromine the nitrous nitrogen is oxidised by the addition of a drop of chlorine water, the total nitrogen being then estimated in the nitric condition, and the amount of nitrates ascertained by difference. Sulphides, sulphides, and acetates do not affect the coloration.—C. S.

Boric Acid, Estimation of. Schneider. Chem. Zeit. 1896, 20, 822.

In order to estimate the amount of boric acid in any substance, the latter is distilled with alcohol and the distillate evaporated with freshly-ignited sodium carbonate, then fused and weighed. The excess of sodium carbonate is determined by a carbonic acid determination, and subtracted from the above weight.

Meat preserved with boric acid offers some difficulties. To obtain the total amount of the acid present, the meat must be chopped up into small pieces, placed in a well-closed beaker, and then cooked by placing in a water-bath. The cooked meat is now rubbed down in a mortar with its own weight of anhydrous sodium sulphate, transferred to a flask, and extracted with alcohol in a reflux apparatus. When the extraction is complete, the alcoholic solution is filtered off and distilled, as already described.—W. P. S.

Aluminium and its Alloys, Analysis of. H. Gouthière. Ann. de Chimie Analyt. i., [14], 265—270. Analyst, 21, [247], 270.

Copper, Nickel, Lead, and Iron.—5 to 10 grms. of aluminium turnings are attacked in successive portions by sodium hydrate solution (1 in 3), in a conical 300-c.c. flask. Brisk effervescence occurs, with evolution of heat, and the operation is complete in about 20 minutes, care being taken to prevent the liquid cooling, or a grey deposit, difficult to dissolve, will be formed. The hot liquid is decanted on to a small filter, and the black deposit very quickly washed five or six times with boiling water, then dissolved in lukewarm dilute nitric acid, evaporated to a syrup, mixed with 2 c.c. of pure nitric acid, and electrolysed at a temperature of 50°—60° C., by the current from three or four Leclanché cells. Both electrodes are of platinum, the negative being a crucible or cylinder, and the positive preferably gauze. In two or three hours all the copper will be deposited as metal on the negative electrode, and the lead on the positive, as PbO₂, the weight of which, multiplied by 0.8661, will give the metallic lead.

The liquid, separated from the copper and lead, is united with the washings, and heated with excess of ammonia, to separate the iron and dissolve the nickel precipitate first formed. When the proportion of the latter metal is large, the iron precipitate should be redissolved in dilute nitric acid, and reprecipitated as before. After filtering and washing with boiling water, the iron oxide is dried, calcined, and weighed. The filtrate is heated, to drive off the excess of ammonia, then slightly acidified with sulphuric acid, concentrated, nearly neutralised by ammonia, and then electrolysed at about 60° C., the nickel depositing in the metallic state on the negative electrode.

Tin, Antimony.—5 or 10 grms. of aluminium are attacked by hydrochloric acid, and after nearly neutralising by ammonium carbonate, a current of hydrogen sulphide is passed, the precipitate formed being collected, washed with hydrogen sulphide water, and digested for some time with warm dilute ammonium sulphide. Then, after filtering and washing with ammonium sulphide water, the soluble sulphides are thrown down by heating. Sulphur is removed by carbon bisulphide. Antimony (which is rarely present) is recognised by the colour of the sulphide. Arsenic sulphide volatilises during calcination, and stannic oxide remains for weighing.

Arsenic.—The sulphides precipitated from 5 grms. of the metal are washed and dissolved in dilute nitric acid. The solution is filtered, evaporated with sulphuric acid until white fumes appear, and then placed in a Marsh apparatus. The gas evolved is passed through a solution of silver nitrate, and the precipitated silver converted into and weighed as silver chloride. This, multiplied by 0.0871, gives the arsenic.

Zinc is precipitated from the hydrochloric acid solution (after removal of the tin, antimony, &c.) by hydrogen sulphide, after adding sodium acetate. The precipitate is washed, calcined, and weighed as ZnO.

Silica.—The solution resulting from the action of hydrochloric acid and 3 c.c. or 1 c.c. of nitric acid on 5 grms. of the metal, is evaporated to dryness until the acid is driven off; the mass is then heated from 110°—120° C., taken up with hot dilute hydrochloric acid, digested for awhile, and after decanting and washing with boiling water, dried and calcined in a muffle.

Total Carbon.—Boussingault's method: chlorination by mercuric chloride, digestion in dilute hydrochloric acid, and heating in a current of hydrogen.

Creak and Ulgreen's method may also be used: solution of the metal in cupro-ammonium chloride, removal of the precipitated copper by hydrochloric acid, and combustion of the residual carbon by a mixture of chromic and sulphuric acids.

Sulphur.—Rollet's method: 2 grms. of the metal are heated to redness in a current of two-thirds hydrogen and one-third carbon dioxide, and the hydrogen sulphide formed, is passed into silver nitrate solution. The silver sulphide is washed and calcined, the silver multiplied by 0.1481 giving the weight of sulphur. A fairly accurate estimate of the silver may be rapidly made by the Eggertz' colorimetric method, noting the effect of the hydrogen sulphide on a silver plate.

Aluminium is generally estimated by difference. It may, if desired, be determined by one of the usual methods, or by that described by Moissan (this Journal, 1896, 136).

The results of 10 analyses of aluminium are given, the chief impurities being lead, iron, and copper. Tin, arsenic, and nickel were only found in two samples.—A. S.

Chrome Yellow and Chrome Red [Lead Chromes], Analysis of. H. Amsel. Zeits. angew. Chem. 1896, 613.

BESIDE the chromate and sulphate of lead of which they essentially consist, commercial chromes are liable to contain barium sulphate and carbonate, calcium sulphate, and chalk. Three processes have been suggested for their analysis: Duvillier's (solution in nitric acid and alcohol), Löwe's (in sodium thiosulphate), and Wittstein's (decomposition with aqueous sodium carbonate), but they are mostly unsatisfactory.

The author's process is as follows:—0.5 gm. of the sample is boiled for 5 or 10 minutes with 10 or 15 c.c. of 10 per cent. caustic potash and 10 c.c. of water. Without filtering, the mixture is strongly acidified with concentrated hydrochloric or nitric acid, boiled again, the barium sulphate filtered off, washed, ignited, and weighed. The filtrate is neutralised with sodium carbonate, bromine water added, the liquid heated on the water-bath till all odour has disappeared, and the lead and calcium removed by filtration. This filtrate is acidified with HCl, and evaporated to dryness to remove the last traces of bromine. The residue is taken up in 30 c.c. of water and a few drops of acid, 5 c.c. of alcohol added, the excess removed, ammonia added, and after 10 or 15 minutes' heating on the water-bath the chromium oxide is filtered off and weighed. The ammoniacal filtrate is then acidified, and the sulphuric acid (from the original lead and calcium sulphates) estimated as usual.

The precipitate of calcium carbonate and lead carbonate or otherwise lead peroxide, is dissolved in HCl, and the two metals separated in the ordinary manner. It is perhaps better to throw down the lead with sulphuretted hydrogen from an acetic acid solution, converting it afterwards into sulphate, in order that any zinc present may be determined in the filtrate. If, however, the lead be free from zinc, it may, provided sufficient bromine was employed to convert the whole of the original lead carbonate into peroxide, be treated with dilute nitric acid, which dissolves the calcium and leaves the lead unattacked. The latter can then be estimated as sulphate, or volumetrically with oxalic acid and permanganate.

The author quotes a number of analyses made of chromes of known composition, and the results he has obtained appear to be very satisfactory.—F. H. L.

ORGANIC CHEMISTRY.—QUALITATIVE.

Tannins, The Knowledge and Classification of. K. Krause. Chem. Zeit. 1896, **20**, 794.

THE tannins or tannic acids may be divided into two classes, *viz.*, tannins not of glucosidal nature, closely related to the oxybenzoic acids (gallic, protocatechuic acids, &c.), and tannins of glucosidal character which are mainly derivatives of substituted oxycinamic acids; these give a green coloration with ferrous salts, changed to violet or red by sodium bicarbonate; and in aqueous solution in the cold, on addition of nitrous acid (Liebermann's reagent), form hydrocyanic acid—a reaction characteristic of many compounds containing the group $\text{CH}:\text{CH}$. For this class of tannins the name "glucotannoids of the cinnaanic acid series," is proposed.

Albumin also forms hydrocyanic acid when acted upon by nitrous acid, and other reactions show it to be an unsaturated compound.—A. C. W.

Beef-Fat in Lard, Note on the Microscopic Detection of. T. S. Gladding. Analyst, 1896, **21**, 254.

THE author finds that in the preparation of crystals of lard and beef stearin for microscopic examination, the following method gives good results, the crystals being of distinctive form:—5 c.c. of melted lard are dissolved in a mixture of 20 c.c. of absolute alcohol and 10 c.c. of ether in a small Erlenmeyer flask, heating gently if necessary. A plug of cotton-wool is placed in the mouth of the flask used, which is then allowed to cool. The stearin crystallises out, leaving the olein in solution. The liquid is filtered rapidly through a paper wet with alcohol, and the crystals washed once with the alcohol-ether mixture (2:1). The crystals, after drying, are removed to the flask and dissolved in 25 c.c. of ether, the cotton plug is replaced, and the flask, resting in a slanting position in a beaker nearly full of water, is let cool over night. Crystals of stearin then separate. The author refers to plates contained in Bulletin No. 13, Part IV., Division of Chemistry, U.S. Department of Agriculture, giving characteristic forms of crystals of lard and beef stearin.—A. S.

ORGANIC CHEMISTRY.—QUANTITATIVE.

Wool-Fat, The Iodine Absorption of. W. Herbig. Dingler's Polyt. J. **302**, [1], 17–23.

IN this paper the author gives a number of determinations of the iodine absorption of an American wool-fat prepared by extracting the raw wool, and also of the fatty acids obtainable from it. He has further determined the iodine absorption of cholesterol (see Lewkowitsch, this Journal, 1892, 142), using excess of iodine.

The fatty acids of the wool-fat were separated into different fractions, and the iodine absorption was determined for each fraction.

A quantity of the fat (about 200 grms.) was saponified with half-normal alcoholic potash in a reflux apparatus, whereby only part of the compound ethers is saponified. After neutralisation, the potassium salts of the fatty acids were converted into the corresponding calcium salts. A portion of these latter are soluble, and are separated by filtration. The insoluble salts, after drying, were further fractionated by extraction with acetone (see this Journal, 1896, 138) into soluble and insoluble salts. The insoluble part consists mainly of saturated acids, whilst that which passes into solution contains the unsaturated acids. The calcium salts soluble in water also contain unsaturated acids. Several determinations of the iodine absorption of pure cholesterol show that, with a sufficient excess of iodine, the maximum absorption, *viz.*, 73.32 per cent., is arrived at after 18 hours' action, the excess of iodine being 45 per cent. of the quantity used. With American wool-fat the absorption is also complete—23.53 per cent.—in 18 hours, the excess of iodine being 77 per cent. The fatty acids obtained from the calcium salts insoluble in acetone, have an iodine absorption of 4.95 per cent., whilst the acids of the soluble salts absorb from 46.69 to 51.79 per cent. of iodine. The iodine values of the fractions obtained from the calcium salts soluble in water, rise to 67.64 per cent.—W. P. S.

Polarisation, Influence of Temperature on [Sagar.] F. Sachs. Zeits. Ver. Rübenzuckerind. 1896, **46**, 264.

THE author found that in the polarisation of raw sugar at temperatures from 14° to 26° C. there were differences of almost exactly 0.1° per 2° C., as Wartze had already observed. But it is not sufficient to note the temperature of the solution polarised and to correct by the above factor unless regard is had to the temperature at which the 100-c.c. flask is made up to the mark. Thus, a normal solution made up and polarised at 25° C. showed a difference, not of 0.5°, but of 0.2° merely. In weaker solutions the influence is obviously still smaller. Finally, Sachs states that the quartz control plates are only very slightly affected by temperature. Pellet (La Suc. Indig. 1896, **31**, 494) is of opinion that the influence of temperature should not be neglected, and that a jacketed tube should be used to keep the temperature constant. He remarks that in order to obtain exact and comparable results, the gas, paraffin, or electric light used should be maintained at the same intensity of illumination. At present this is by no means the case, even with monochromatic flames, so that differences may be obtained of 0.2 to 0.5 in the readings. It appears, therefore, of advantage to have an arrangement to determine readily the intensity of the light used, and he describes one similar to that used in photography to study the sensitiveness of paper. Black numbers are written on a glass plate, and these are covered with layers of thicker or thinner paper. It is so arranged that before a polarisation the numbers must always be visible which are covered with, say, four layers of paper.

—L. J. de W.

Basic and Neutral Lead Acetate, Influence of, upon the Polarisation of Sugars. H. Pellet. Bull. de l'Assoc. des Chim. de Sucre et de Dist. 1896, **14**, 131–145.

THE author finds that whilst basic and neutral acetate of lead do not appreciably affect the rotatory power of aqueous solutions of cane sugar, yet the basic salt diminishes the rotation in alcoholic solution in proportion to the amount of alcohol present, or in the presence of certain salts, such as chlorides, &c. Solutions of levulose are acted upon by basic acetate of lead; and, according to the amount added and the concentration of the levulose solution, the rotatory power may be 0° or even dextro-rotatory. Consequently, in the presence of basic acetate, juices and solutions of syrups and molasses containing a small percentage of levulose may have a direct polarisation equal to or greater than that observed after inversion. In such cases the addition of acetic acid produces a normal rotation. The presence of salts favours the precipitation of levulosate of lead. Neutral acetate of lead does not affect the rotatory power of levulose, even when in the presence of considerable quantities of salts. Dextrose is unaffected either by the basic or neutral acetate; in alcoholic solutions more levulose than dextrose is precipitated. From these observations it is apparent that basic acetate of lead should never be used in the presence of alcohol for the analysis of sugar products. Conditions obtain which may bring about decompositions favouring the diminution of rotatory power or the precipitation of sugar. Differences in results of observers also arise from the degree of basicity of lead acetate. An excess of basic lead acetate diminishes the rotatory power of raffinose, either when the solutions are alcoholic or when salts are present; but in weak solutions, and especially in the presence of cane-sugar, raffinose remains unaltered.

In aqueous solutions of molasses the author finds that the polarisation is raised in proportion to the excess of basic lead acetate added; the reducing power, on the other hand, is diminished on account of the levulose, either alone or with the dextrose, having been precipitated. Neutral lead acetate may be used for defecating aqueous solutions of molasses, the excess of lead being removed by sulphurous acid.

Invert sugar behaves as a mixture of levulose and dextrose towards basic lead acetate; the varying rotatory powers observed are due only to the levulose.

In analysing cane molasses, whatever may be the lead reagent employed, the direct polarisation should be observed in a solution rendered strongly acid with acetic acid, so

that a reading may be made comparable with that of the inversion; polariscopic readings should also be taken at the same temperatures before and after inversion.

In the estimation of reducing powers it is advisable to employ a half per cent. solution, as in this concentration the sulphurous acid used for the elimination of lead does not influence the reduction (this Journal, 1896, 746).—J. L. B.

Defecated Sugar Liquors, Precipitation of Lead in. Zamaron. Bull. de l'Assoc. des Chim. de Sucre et de Dist. 1896, 14, 181—182.

According to the author, the excess of basic lead acetate may be conveniently removed by ammonium oxalate in solutions of molasses containing more than 0.3 per cent. of reducing sugar. It is considered difficult to estimate amounts less than 0.3 per cent. of glucose, and it is proposed in such cases to add a known quantity of glucose or invert sugar to 100 grms. of molasses, to estimate the reduction by the copper method, and to correct the number so obtained for the known amount of added reducing sugar present.—J. L. B.

Beetroot Juice, Determination of Free Alkali in. J. Cotrait. Bull. de l'Assoc. des Chim. de Sucre et de Dist. 1896, 14, 182—183.

The author finds iodide of starch to be a convenient indicator for caustic alkali, and, unlike phenolphthalein, it is not influenced by ammonia or alkali carbonates and bicarbonates. 25 c.c. of clear or thick juice is placed in a beaker, together with a little starch paste and four or five drops of tincture of iodine. If the alkalis present are in a state of carbonate, the liquid, when shaken, becomes intensely blue; but, if they are caustic, a colourless alkaline hypo-iodide is formed, which is decomposed by an acid, without influence on iodine of known titre. A correction is made for the quantity of iodine added which behaves as an acid.—J. L. B.

Raw Sugars, Determination of Water in. Herzfeld. Sugar Cane, 1896, [321].

The author has shown that when pure sugar, combined with 3 per cent. or more of pure water, is heated for 3—5 hours in a current of dry air at 105°, the whole of the moisture is lost. Drying *in vacuo* does not offer perceptible advantages; care should only be taken to increase the temperature slowly. If the sugar is combined with water containing inorganic salts or organic non-sugar, such as in the case of raw sugars, a loss of acids and volatile bases occurs when they are heated to 108° in a current of dry air or gas free from oxygen. When the sugar has an alkaline reaction, carbon dioxide is liberated from the bicarbonate formed during carbonation, or by the action of sugar on neutral carbonate. According to Gunning (this Journal, 1895, 338), the content of carbon dioxide in raw sugars does not exceed 0.07 per cent.; with white or nearly white sugars, this number often falls to 0.03 per cent., whilst if the sugar be slightly acid the maximum will be 0.01 per cent. The proportion of volatile bases is much smaller—in terms of ammonia 0.002 per cent.; these are not exclusively produced from ammonia, for when converted into neutral sulphates, an amount higher than that given by Nessler's solution is obtained. Beetroot sugars, being generally acid, evolve very little carbon dioxide, but give off a considerable quantity of fatty acids. It is recognised that these acids are not formed during desiccation; they pre-exist in the sugars, for after drying they become neutral. The inverse phenomenon is observed in sugars from the cane. The author recommends that raw beetroot sugars should be dried by heating for five hours to 108° in a current of dry air.

With cane sugars the estimation of moisture is complicated by the presence of levulose, and of organic non-sugar possessed of particular properties; the former losing water and becoming converted to levulose (this Journal, 1895, 338). Therefore raw cane sugars containing levulose, when heated to 108°, lose hydrogen and oxygen, which do not form part of the moisture. The organic non-sugar also gives rise to acids, thus augmenting the

amount of levulose. The only method available with cane sugars is to heat *in vacuo* at a maximum temperature of 95°.—J. L. B.

Starch, A Study of Methods for the Determination of. H. C. Sherman. School of Mines Quart. 1896, 17, [4], 356—365.

In discussing the principal methods which have been proposed for the estimation of starch, the author points out that in many of them the high results obtained are due to the susceptibility to hydrolysing agents of the pentosans, xylan, and araban. The diastase method affords satisfactory results, and it cannot be vitiated by the presence of pentosans, glucosides, or any substances known to occur in cereals or the more common grasses. The following method, which is due to Reinke, is carried out by boiling the sample, previously freed from soluble matter, with water, to completely gelatinise the starch. The solution is cooled to 62° C., malt extract is added, and the whole kept at this temperature until the iodine reaction has vanished. It is then filtered, washed, and the filtrate inverted by boiling for 30 minutes with one-tenth its volume of 25 per cent. hydrochloric acid. The glucose is determined according to Saehsse's method.—J. L. B.

Caseine in Milk, A Rapid Volumetric Method of Determining. Denigès. Bull. Soc. Chim. 15, [18—19], 1116—1126.

1r to 10 c.c. of decinormal potassium cyanide solution there be added 10 c.c. of decinormal mercuric-potassium iodide, 10 c.c. of ammonia solution, and 100 c.c. of water, then on adding decinormal silver nitrate, a turbidity of silver iodide appears when 4.8 c.c. have been added, instead of 10 c.c., owing to the mercury appropriating some of the potassium cyanide, and thus preventing it from forming the silver compound.

If milk be previously added to the mercury salt, the caseine is precipitated along with a portion of the mercury; and on now adding silver nitrate a larger amount than 4.8 c.c. is needed (owing to the greater quantity of free potassium cyanide present) before the turbidity of silver iodide appears. The difference between this amount and 4.8 c.c. gives a measure of the caseine in the milk taken.

Taking for analysis different quantities of the same milk, or equal quantities of milks of different caseine-content, it was found that the result given by this method (as compared with the result by the gravimetric method of Adam and Roux) was too low where the amount of caseine was small, and too high where it was large. A curve and a table of differences were therefore constructed from the results of analysis of a number of known samples; and the results interpreted by this curve, in the cases of a large number of samples of milk of different origin, and also of cooked and sterilised milks, agree very closely with those obtained by the gravimetric method.

For details of these comparisons, and of the precise way in which the method is to be carried out, the original paper should be consulted.—J. T. D.

Zinc, Determination of, in Foods. Janke. Chem. Zeit. 1896, 20, 800.

The difficulty in the determination is to remove the organic substances from the large quantity of material required. The author's method, which is not lengthy, is as follows:—50—100 grms. of substance, cut in thin slices, are dried at 125° for three hours; the dark brown mass is powdered and mixed with 25 c.c. of nitric acid (sp. gr. 1.31) and 10 c.c. of strong sulphuric acid. When the violent action is over, the residue may be easily burnt; this must be done, at the most, at an incipient red heat, for higher temperatures will cause loss of zinc; this part of the process may last four hours. The ash is evaporated with a little hydrochloric acid, the residue dissolved in water, exactly neutralised by sodium bicarbonate, and the iron, aluminium, and phosphoric acid precipitated by sodium acetate and acetic acid. In the filtrate the zinc is precipitated as sulphide; the zinc sulphide must be dissolved and reprecipitated.

tated if it is not quite free from iron. The percentage of the zinc present found by this method, lies between 98.8 and 104.5, the total amount of zinc varying from 0.01 to 0.05 grm.—A. C. W.

Formaldehyde, Detection and Quantitative Estimation of.
F. C. J. Bird. Pharm. J. 1896, 57, 269—271.

Nessler's reagent gives a distinct yellow precipitate with a solution containing 1 part of formaldehyde in 200,000. With solutions of 1 part in 50,000 to 100,000, a yellowish opalescence first appears, quickly changing into a copious orange precipitate, which on standing or gently heating, becomes darkened in colour and reduced. From 1 in 100,000 to 1 in 200,000, the opalescence develops into a lemon-yellow precipitate on standing, and little or no reduction takes place. The effect produced by formaldehyde is quite distinct from that of a weak solution of ammonia, giving about the same depth of colour, as the latter remains quite clear and transparent, even on boiling. With strong solutions of acetaldehyde, an orange precipitate and immediate reduction occur, the same as with formaldehyde, but traces hardly affect Nessler's reagent, and even when it is in sufficient quantity to communicate its odour to the liquid, a yellow precipitate is the only result. Its reaction is very much less energetic than that of formaldehyde, and the two aldehydes can easily be distinguished from one another when only traces, such as would be met with in the ordinary course of analysis, are present (see also this Journal, 1896, 382 and 772).

The Ammonia Micro Test (Remijn).—The substance or liquid under examination is distilled with water, a drop of the distillate evaporated on a slide with a drop of ammonia, and the crystalline residue tested with mercuric chloride in excess. Crystals are immediately formed, hexahedral at first, but becoming octahedral after a time. The crystals are easily obtained from a 1 in 10,000 solution, and are visible in a 1 in 100,000 solution. The evaporated residue also gives precipitates with platinum chloride, phosphomolybdic acid, and other alkaloidal reagents.

Quantitative Determination.—(1.) Titrate the solution with standard ammonia, using rosolic acid to indicate the complete conversion of the formaldehyde into hexamethylene-amine. (2.) Add excess of standard ammonia, and titrate back again with standard acid. (3.) Evaporate to dryness with excess of standard ammonia, and weigh the hexamethylene-amine formed, calculating the formaldehyde from the following equation:—

(4.) Heat for several days in a closed vessel on a water bath with excess of sodium hydrate; sodium formate and methyl alcohol are produced, and the excess of sodium hydrate may be determined by titration with acid (Allen). As the whole of the formaldehyde cannot be separated by distillation, even when three-fourths of the volume of the liquid containing it has been collected as distillate, the first four of the foregoing methods, if accurate results be desired, are only applicable to solutions in which no other interfering constituent exists. A method for completely removing the formaldehyde, is apparently necessary for its exact quantitative determination in complex mixtures.—A. S.

Wood Pulp in Paper, Some Methods for the Detection and Estimation of. Wood Pulp, 1, [3], 1896, 61—64.

The detection of wood pulp in paper is easily performed by the aid of the microscope, but a trustworthy method for the exact estimation of either chemical or mechanical wood pulp is not so easily found. In the case of ground wood the following methods give fairly accurate results, if the experiments are carefully conducted.

Microscopical Examination.—Small pieces of paper are cut from different parts of the sample to be tested, and are boiled for a short time in a 1 per cent. solution of caustic soda. The fibres are then separated in a mortar, or by shaking them in a bottle containing a few pieces of broken glass; or a better way is to soak the paper in glycerin, and tease it out with needles, when it will be ready for examination. In the former cases the fibres are placed on the glass

slide, and covered with a drop of glycerin or solution of Canada balsam in benzene, and a cover glass.

Under the microscope, chemical wood pulp appears as flat, riband-like fibres, showing unbroken ends, not unlike cotton, but distinguished from the latter by not being twisted. The presence of small pitted vessels in the fibres is characteristic of pine wood. Mechanical wood is distinguished from chemical wood pulp by having the ends of the fibres torn and jagged, and by the fact that the fibres are rarely separated, but are generally bound together in bundles by the incrusting substances. The pitted vessels before referred to are generally more distinct than in chemical pulp.

Chemical Examination.—The use of certain chemicals and colours is useful in indicating the presence of certain fibres, and in assisting to bring out more clearly the characteristics of the various fibres. Dilute solutions of the aniline colours are very suitable for the latter purpose.

Nitric Acid, concentrated, produces a characteristic brown stain on paper containing mechanical pulp, and outside the laboratory this is the indication most generally used.

Aniline Sulphate.—A saturated solution of the salt in alcohol gives a deep yellow coloration with a ground wood. It may be added, however, that imperfectly boiled and bleached chemical pulp will be coloured by these reagents.

Phloroglucinol, prepared by dissolving 2 grms. of the reagent in 25 c.c. of alcohol, and adding 5 c.c. of concentrated hydrochloric acid, gives a deep magenta coloration, which is very characteristic of lignified tissues.

Iodine is absorbed from its solutions in potassium iodide in large quantity, colouring the fibre a deep brown.

Chlorine combines with the fibre with avidity; the chlorination is made evident with sodium sulphide solution, which develops a deep magenta coloration.

Ferric chloride colours the fibre substance to a dark greenish tint, the reaction being due to traces of tannins.

Ferric ferriyanide, the red solution obtained by mixing together ferric chloride and potassium ferriyanide in equivalent proportions, gives a highly characteristic reaction, the fibre substance rapidly decomposing the compound to Prussian blue.

Potassium permanganate is rapidly reduced, the MnO_2 produced, colouring the fibre a deep brown.

The above tests apply to lignified fibres generally.

The following is said to be of use for the detection of sulphite pulp:—A dilute solution of sodium auric chloride is employed, and a little of the paper moistened with it. With unbleached sulphite cellulose it gives a red-brown colour, whereas with bleached sulphite and soda cellulose it gives a bluish colour.

Estimation of Chemical Pulp.—The only trustworthy method of estimating the amount of chemical wood pulp present in a sample of paper, is by making a number of examinations under the microscope, actually counting the various fibres in the field, and averaging the results. In identifying the fibres, iodine and sulphuric acid will be found to be of assistance.

Estimation of Mechanical Pulp.—This may be done with fair accuracy by the comparison of the depths of colour obtained by the qualitative tests already given. A standard set of samples is prepared, containing known proportions of ground wood, and the colours obtained by treating these with aniline sulphate, nitric acid, or phloroglucinol, are compared with the colours obtained by treating the sample with the same reagent. These tests indicate lignified fibre, so that if jute or imperfectly reduced sulphite fibre were present, they would be rendered inaccurate.

Several other methods have been suggested, for example: by the volume of chlorine disappearing in chlorination; by the estimation of furfural; by methyl estimations, in the absence of straw and esparto; and by a method discovered by Wurster, *viz.*, the oxidation of the methylated derivatives of paraphenylenediamine to red colouring matters. The reagent is incorporated with a pure cellulose paper, and this is pressed into a moistened piece of the sample under examination. The depth obtained is compared with a colour scale, and the percentage of ground wood calculated from it.

In Godeffroy and Coulon's method two equal portions of paper are taken, boiled in 10 per cent. ammonia, then washed and dried. One portion is burned and the ash determined. The other portion is boiled with a solution of gold chloride, washed, dried, burned, and the residue weighed, and from this is deducted the weight of ash from No. 1, which leaves the weight of the reduced gold, and from this is calculated the quantity of ground wood present, 100 parts of wood reducing 21.2 parts of gold.

The microscopic estimations and the colour tests will, however, generally be found to give sufficiently accurate results for practical purposes.—S. P. E.

Bismuth Salicylate, Testing of [for Free Salicylic Acid]. Pharm. J. 1896, 4, 215.

DOTT (Pharm. J. [3], 25, 582) has drawn attention to the fact that commercial bismuth salicylate contains uncombined salicylic acid. The free acid may easily be determined by the following method:—A known weight of the salt is digested in cold methylated spirit, filtered, and the filtrate evaporated to dryness in a tared vessel, when the free acid will be left as a residue, which may be weighed. A sample has been met with containing more than 50 per cent. of uncombined acid; this was of exceptionally "good colour," and further examination of light-coloured samples showed that these invariably contained more than traces of free acid (this Journal, 1895, 295).—A. S.

Salicylic Acid, Quantitative Determination of. F. Freyer. Chem. Zeit. 1896, 20, 820—821.

WHEN the tetra-bromide obtained by treating phenol with bromine water is acted on by potassium iodide, substitution takes place and iodine is liberated, as shown in the equation:—

A similar reaction takes place with the compound formed from salicylic acid.

To test the reaction as regards its suitability for the quantitative determination of salicylic acid, experiments were made as follows:—5.071 grms. of pure calcium salicylate are dissolved with the addition of a little hydrochloric acid and diluted with water to 1 litre. This solution then contains 4 grms. of salicylic acid. A solution containing 1.7 gm. of potassium bromate and 6 grms. of potassium bromide, a 10 per cent. solution of potassium iodide and a $\frac{1}{10}$ N thiosulphate solution, are also required. 100 c.c. of bromate solution correspond to 0.138 gm. of salicylic acid. Of this solution, 100 c.c. are diluted with an equal bulk of water, 20 c.c. of dilute hydrochloric acid added, and then 10 c.c. of the salicylic acid solution. After three or four minutes 15 c.c. of the potassium iodide solution are added, and the liberated iodine titrated with $\frac{1}{10}$ N thiosulphate solution. A check experiment is made without the addition of salicylic acid, and the difference between this figure and the one obtained above calculated into salicylic acid.

If starch solution be used in the titration, it must not be added until the reaction is almost complete, as the flocculent precipitate present encloses the blue starch iodide, and the solution is liable to be over titrated before the blue tint disappears.

Analyses carried out in the above manner with varying quantities of salicylic acid, gave results which only varied 0.5 per cent. from the amounts of acid taken.

The author also gives the results of experiments made with regard to the delicacy of the ferric chloride reaction with salicylic acid. 100 c.c. of wine preserved with this substance were distilled off as far as possible, the distillate collected in separate portions, and tested with ferric chloride. The experiments show that none of the salicylic acid comes over in the first 50 c.c., the characteristic coloration being obtained in the latter portions of the distillate. Wine containing 0.001 per cent. of salicylic acid gives no coloration with ferric chloride. As the acid only comes over towards the end of the distillation, the testing for this substance may be combined with the alcohol determination, the latter being collected in the first portion of the distillate. The author is unable to confirm the statement made by Horn (Chem. Centralbl. 1888, 1125) that beer, known to be

free from salicylic acid, yields a distillate which gives a violet colour with ferric chloride, and asserts that the above distillation method is quite applicable for testing this beverage.—W. P. S.

Morphine in Opium, Determination of. G. Loof. J. Pharm. Chim. 1896, 16, 312.

SALICYLATE of soda is found to be an excellent precipitant for the resins in opium; a portion of the narcotine is also thrown down; this may be extracted from the dried precipitate by benzene. The following is the procedure in a determination of morphine:—6 grms. of finely powdered opium are triturated with 6 grms. of water and washed into a tared flask, the total weight of liquid being made up to 51 grms.; after shaking for 15 minutes the liquid is filtered through a folded filter, 42 grms. of the filtrate are taken, and 1 gm. each of sodium salicylate and water added. On shaking, the precipitate collects into a compact mass; after filtering, to 36 grms. of the filtrate, there are added 4 grms. of ether and 1 gm. of ammonia, and the whole is well shaken for 10 minutes. The morphine is precipitated and does not adhere to the sides of the flask; it is transferred to a filter; the flask is twice rinsed out with 5 grms. of water; after drying, the morphine is washed with benzene, and finally dried.—A. C. W.

XXIV.—SCIENTIFIC & TECHNICAL NOTES.

Hyponitrous Acid. Hantzsch and Kaufmann. Annalen, 292, [3], 317—340.

ZORN'S process was employed, whereby a solution of sodium nitrite and caustic soda was caused to act upon sodium in the form of sodium amalgam. Thus silver hyponitrite was produced. The action was, however, conducted at a low temperature, and the amalgam added very gradually. The filtered solution was precipitated by silver nitrate, and the yellow precipitate purified by repeated solution in weak nitric acid and reprecipitation by ammonia. From this salt hyponitrous acid was prepared by precipitation with hydrochloric acid in ethereal solution. The acid appears on evaporating the ether in white crystalline plates. It is extremely unstable, exploding, when dry, on the slightest touch, though much more stable in aqueous solution. The molecular weight, as determined by the lowering of the freezing point, agrees with the formula $H_2N_2O_2$. The acid, both in the behaviour of its salts and its conductivity for electricity, is similar to carbonic acid.—J. T. D.

Bromides, The Double. R. Varet. Comptes rend. 1896, 123, 497.

THE heat evolved by the union of mercuric bromide with the bromides of mono- and divalent metals in solution, was measured. These compounds have heats of formations which are of the same order of magnitude for the same series of double salts; the differences are due to the unequal thermal effects of dilution in the different cases. These double bromides must be regarded as derivatives of the acids H_2HgBr_2 and H_2HgBr_4 .

The salts formed by the union of cobalt and manganese bromides with the alkaline bromides, suffer considerable dissociation on dialysis; their formation in the state of solution is not accompanied by appreciable thermal effects.

—A. C. W.

Mercury, Oxy-Salts of. Varet. Bull. Soc. Chim. 15, [18—19], 1081—1086.

A THERMO-CHEMICAL study. The oxy-salts of mercury obey the usual thermo-chemical law of substitutions, i.e., the evolution or absorption of heat when the mercury exchanges with another metal, is independent of the particular acid of the salt.

Mercuric nitrate exists in solution as the normal salt.

Mercuric sulphate, dissolved in excess of sulphuric acid, behaves exactly like the corresponding sodium or potassium salt, i.e., is in a state of partial dissociation—a fact demonstrable by dialysis.—J. T. D.

Basic Nitrates. Athanasesco. Bull. Soc. Chim. 15, [18—19], 1078—1081.

Digestion of normal lead nitrate with ammonia, even for a year, does not yield the salt $\text{Pb}(\text{NO}_3)_2 \cdot 5\text{PbO} \cdot 11\text{H}_2\text{O}$, but only a tetrabasic salt, $4\text{PbO} \cdot \text{N}_2\text{O}_5 \cdot 21\text{H}_2\text{O}$. The first-mentioned salt is, however, obtained by a year's digestion with strong ammonia of the salt $\text{PbOH} \cdot \text{NO}_3$, obtained by boiling the solution of normal nitrate with litharge.

Normal zinc nitrate in strong solution, heated alone or with a little zinc oxide in sealed tubes to 310° , yields nearly needles of a salt having the formula $4\text{ZnO} \cdot \text{N}_2\text{O}_5 \cdot 31\text{H}_2\text{O}$.

Partial precipitation of normal zinc nitrate with ammonia yields no definite salt, but mixtures varying with the amount of ammonia.

Boiling strong solution of zinc nitrate with zinc gives another definite basic nitrate of the formula $4\text{ZnO} \cdot \text{N}_2\text{O}_5 \cdot 4\text{H}_2\text{O}$. Constitutional formulae of these salts are suggested.

—J. T. D.

Diamonds in Steel. L. Frank. Stahl u. Eisen, 1896, 16, 585.

MINERALOGICAL evidence points to the diamond being a product of high temperatures. Moissan showed that diamonds could be produced by chilling melted iron containing carbon with the aid of the pressure of the solidified outer crust. Rosel considered that all steel contained diamonds (see this Journal, 1896, 682). The author now states that nearly all varieties of steel contain more or less considerable quantities of crystallised, transparent carbon. The diamonds may be extracted by dissolving the steel (300 grms.) in nitric acid, and treating the residue successively with boiling hydrochloric and hydrofluoric acids, with sulphuric acid, with fused potassium chlorate, with acids again, and finally with bromoform. The diamonds are minute octahedra, and sink in methylene iodide. Hammered or rolled steel shows only fragments and splinters. It is of especial interest to note that the largest artificial diamonds yet found have been met with in a mass taken from the hearth of a blast furnace. The iron diamonds are usually very brittle, and tend to break off their own accord.—W. G. M.

Nickelo-Nickelic Hydrate, $\text{Ni}_3\text{O}_3 \cdot 2\text{H}_2\text{O}$. W. L. Dudley. J. Amer. Chem. Soc. 18, 10, 900—903.

This compound is prepared by fusing sodium dioxide in a nickel crucible with metallic nickel at a cherry-red heat. It appears that in order to obtain the new substance absolutely pure it would be necessary to use a crucible of absolutely pure nickel, owing to the activity of sodium dioxide, which oxidises the small quantity of cobalt present in the nickel of commerce.—V. C.

Melezitose, Hydrolysis of, by Soluble Ferments. E. Bourquelot and H. Hérissé. J. de Pharm. et de Chim. 1896, 16, [6], 385—387.

ALEKHINE (Bull. Soc. Chim. 1877, 27, 98) has shown that melezitose is a hexatriose isomeric with raffinose: the authors have endeavoured to ascertain if this sugar-like raffinose is hydrolysed by soluble ferments. The purified melezitose when dried at 100° , melted at 148°C , was non-reducing, and had a specific rotatory power of $[\alpha]_D^{20} 88^\circ 15$. No birotation was observed. A solution of the sugar treated with an aqueous extract of *Aspergillus niger* for three days reduced Fehling's solution strongly, whilst the rotatory power had sunk to $61^\circ 2$. With acids, the hydrolysis of melezitose takes place in two phases—in the first to dextrose and touranose, the mixed products rotating $[\alpha]_D^{20} +63^\circ$; in the second, the touranose becomes converted into two molecules of dextrose. It thus appears that the authors have attained the limit of the first phase.

—J. L. B.

Aldazine, Ketazine, and the Benzosazones of Aldoses and Ketoses. E. Davidis. Ber. 1896, 29, 2308—2311.

A GENERAL method for the preparation of aldazines and ketazines of the sugars consists of treating the carbohydrate with a slight excess of hydrazine hydrate and warming the mixture with methyl alcohol. Glucose-aldazine, which may

be taken as a type, is a white hygroscopic microcrystalline powder, soluble in water and methyl alcohol, but insoluble in ether, chloroform, and benzene. Decomposition with acid shows that the compound consists of one molecule of hydrazine combined to two of the sugar, so that it has the composition $(\text{CH}_2\text{OH})_6 : [\text{CH}(\text{OH})]_6 : (\text{CH} : \text{N} : \text{N} : \text{CH})$.

The benzosazones of aldoses and ketoses are prepared by heating benzhydrazide and the sugar in a weak alkaline solution. These compounds differ from the phenylsazones in that one molecule of the sugar condenses with four molecules of the hydrazide. Thus the composition of glucosebenzosazone is expressed by the formula—

—J. L. B.

Developer, Photographic, Occurrence of Luminosity in Use of. A. Helheim. Phot. Arch. 1896, 37, 203.

A GELATINO-BROMIDE plate was half-developed in a solution of 1 of pyrogallol, 1.5 of sodium carbonate, and 2 of formaldehyde (a 40 per cent. solution) in 30 of water, and then laid aside. After a few minutes a strong glimmering light was observed on the plate; it was strongest at the edges, but soon became equally bright to the centre. The phosphorescence appeared when the solution had been completely absorbed by the film, so that the surface had become dry. The light lasted for several minutes; it was bluish-white, and so strong that it was visible even in that of the dark room lantern. The addition of 30 c.c. of alcohol, as a dehydrating agent, to the developer itself produced in the flask a very strong phosphorescence, which soon faded, but became stronger again on shaking. This indicates that the phenomenon was independent of the presence of the gelatin plate.—W. G. M.

New Books.

CHEMIKER-KALENDAR, 1897. Von Dr. RUDOLF BIEDERMANN. 18ter Jahrgang. Mit einer Beilage. Julius Springer, Berlin. H. Grevel and Co., 33, King Street, Covent Garden, London. 1896. Price 4s. 6d. post free.

THIS pocket book for chemists, analysts, and technologists now appears in its 18th annual edition. It is strongly bound in cloth, contains an almanack for 1897, and a table of frequently used atomic weights and their multiples. A Chronological Table is added of the principal events in the history of the Sciences, more especially of Chemistry. A Note-book Calendar is also supplied, with blank pages for the different days of the year, wherein notes, data, &c. may be recorded. Tables next follow of specific gravities of Gases, and Liquids, Salts and Alcohols. Tables also of Solubilities and Properties of Inorganic Chemical Substances; another set being devoted to similar data for Organic Substances. The remainder of the little book is devoted to tabulated data as to Qualitative and Quantitative Chemical Methods, Volumetric Analysis, Spectrum Analysis, Gas Analysis, and Mineralogy. The Supplementary Volume or "Beilage zum Chemiker-Kalendar" is virtually a pocket book more especially designed for technologists. After some data, statistics, &c., of mathematical, physical, and general interest, the following groups of subjects receive special attention:—I. Water. II. Assaying. III. Fuels. IV. Sulphuric Acid. V. Alkali. VI. Bleaching Powder. VII. Nitre and Explosives. VIII. Ceramic Arts. IX. Glass. X. Mortar and Cement. XI. Illuminating Gas. XII. Starch and Sugar. XIII. Fermentation Industries. XIV. Fats and Oils. XV. Tannins. XVI. Textile Fibres, Paper. XVII. Photography. XVIII. Colours and Dyes. XIX. Physiological-Chemical Analysis. Various useful recipes are finally given.

CHEMISCH-TECHNISCHES REPERTORIUM. Uebersichtlicher Bericht über die neuesten Erfindungen, Fortschritte und Verbesserungen auf dem Gebiete der technischen und industriellen Chemie, mit Hinweis auf Maschinen, Apparate und Literatur. Herausgegeben von Dr. EMIL JACOBSEN. 35. Jahrgang. 1896. Erstes Halbjahr. Erste Hälfte. Mit in den Text gedruckten Illustrationen,

Hermann Heyfelder, R. Gaertner, Schönabergerstr. 26, Berlin. A. Grevel and Co., 33, King Street, Covent Garden, London.

THE first issue for the first half-year of 1896, of Dr. Jacobson's *Repertory of Chemical Technology*, containing reports of the progress of the following branches of chemical industry:—I. Building Materials, Cements, &c. II. Dye-stuffs, Dyeing and Calico Printing. III. Fats, Oils, Illuminating and Heating Materials. IV. Fermented Liquors. V. Tanning, Leather and Glue Manufacture. VI. Textiles. VII. Glass and Earthenware. VIII. Wood and Horn. IX. India-Rubber and Gutta-Percha. X. Cements and Adhesives. XI. Lacquers, Varnishes, and Paints. XII. Metals.

THE DEVELOPMENT OF THE PERIODIC LAW. F. P. VENABLE, Ph.D., F.C.S., Professor in the University of North Carolina. Chemical Publishing Co., Easton, Pa., U.S.A. 1896. Price 2/50 dols.

SMALL. 8vo volume, containing prefatory sketch, subject-matter covering 281 pages, a bibliographic index to the literature relating to the Periodic Law, filling 24 pages, a list of authors alphabetically arranged, and a general alphabetical index to the volume. The general scheme of the work may be gathered from the following abstract of the leading contents:—I. Prout's Hypothesis and the Dobereiner Triads. II. Dumas and the Period from 1850 to 1860. III. The Immediate Forerunners of the Periodic Law. IV. The Announcement of the Periodic Law (1869—1871). V. Development of the Systems (1870—1880). VI. The Development of the Natural Law (1880—1885). VII. Ditto (1885—1890). VIII. Ditto (1890—1896). The work is illustrated with diagrammatic charts, &c.

CHEMISTRY FOR BEGINNERS. By EDWARD HART, Ph.D., Professor of Chemistry, Lafayette College, Easton, Pa. Third Edition, revised and greatly enlarged. Chemical Publishing Company, Easton, Pa., U.S.A. 1896. Price 1/50 dols.

SMALL. 8vo volume, containing preface, table of contents, subject-matter filling 224 pages, and an alphabetical index. The text is illustrated with 62 engravings and 2 plates.

The work is divided into three sections, devoted as follows:—I. Non-metals; II. Metals; and III. The Carbon Compounds.

Tannin powder, being an extract from nut galls in the form of a powder, is liable to duty as tannin or tannic acid at 60 cents a pound under paragraph 5 of the same Act.

Carbonate of potash is entitled to a free entry under paragraph 595.

Sarsaparilla is entitled to free entry under paragraph 555, which enumerates on the free list, among other articles, "lemonade, soda water, and all similar waters."

Potash water is free of duty under the same paragraph.

Ground carbonate of baryta (witherite), is to pay duty at 20 per cent. *ad valorem* under section 3.

VICTORIA.

Classification of Articles in Customs Tariff.

Tariff No.	Description of Articles.	Rate of Duty.
495	Medicated preparations containing alcohol:— Succus taraxaci, over 25 per cent. Strophanthus, tincture of, 44-6 over proof. Tonic verumifuge, Jayne's, over 50 per cent.	12s. per gallon of the strength of proof by Sykes' hydrometer, and so in proportion for any greater or less strength than the strength of proof, when not dutiable at a higher rate under the heading of Medicines liable to 25 per cent. <i>ad val.</i>
295	Medicines, &c.:— Balsamic amykos aseptic, recommended. Creosote carbonate or creosotal is a chemical, in packages of 1 lb. Ichthyol, in 1-oz. bottles Phenacetine, in 1-oz. bottles, Phenazone, Swiss (being another name for antipyrin), consists of ingredients in chemical combination, and when not packed for retail sale or recommended.	25% <i>ad val.</i> Free. Free. Free.

GENERAL TRADE NOTES.

TIN-PLATE INDUSTRY IN PENNSYLVANIA.

Journal of the Franklin Institute, 1896, 142, 315.

In Pennsylvania there are 17 tin-dipping works, and 10 others where black-plate is manufactured as well; they employ altogether about 3,000 persons. The total produce of the State for the year ending December 31 last was 104,375,366 lb. of finished tin- andterne-plate, representing roughly one half the entire capacity of the American factories. The average value of both materials was 81.20 dols. per nett ton, and of the tin-plate alone, 89.62 dols. per ton. The plants were in operation about 240 days during the year; and the average daily wage of skilled and unskilled labour in the two classes of works was 1.79 dols., or 1.38 dols. in the dipping works only.—F.H.L.

COAL AND SALTPETRE IN SOUTH AFRICA.

Imperial Institute Journal, November 1896, 402.

If reports are reliable, Namaqualand holds forth glorious prospects for enterprising miners. Discoveries of copper and coal are reported, and news comes from the Karoo that a bed of nitrate of potassium at least 15 feet thick, covering 50 square miles, has been found and can be worked to pay. The bed lies in the Newveld district, and the main railway line runs through it. Again, conveniently situated almost on the line of the new railway, a discovery of coal has been made about 25 miles due north of Pretoria. This discovery is likely to prove valuable, as the quality of the coal is reported to be excellent. Something like 1,000 square miles of coal are supposed to be in the wide district traversed by the railway between Pretoria and Delagoa Bay, and in the midst of these coal-beds is the outcrop of iron ore. In one colliery not six miles from Johannesburg, coal 70 ft. in thickness has been found.

THE GOVERNMENT METALLURGICAL WORKS IN NEW SOUTH WALES.

The metallurgical works of the New South Wales Government were to have been in active operation before the end of September, according to the *Australian Mining Standard*. They are situated on the Duck River, not far from Parramatta. By some inexplicable oversight cyanide and chlorination works were omitted from the original plan, but these are now to be added. The crushing and amalgamating machinery is nearly complete. The regulations and scale of charges have been prepared, and will be issued by the department in the course of a few days. They provide that bulk samples of gold ores up to 10 tons in weight from any one mine, or distinctive section of a mine, will be received with a view of determining the value of the ore, and the best and most economical method to be adopted for

its treatment. Cases of prospectors who are not in position to pay for testing their ores have been taken into consideration, and the Minister has approved of parcels being treated for them at the works free of charge. The only conditions to be attached to such a concession are that the applicants will get the ore, bag it, and place it on trucks at the nearest railway station, the department defraying the cost of railway carriage and treatment. Should the stone, however, yield any metal of value it will go towards the cost of the treatment. A report will be furnished to the owner in each case, showing the process to which the ore has been subjected, and offering suggestions as to the best and most economical methods of dealing with it, so that the loss of metal may be reduced to a minimum. The charges for crushing, sampling, assaying, amalgamating, and concentrating gold ores will be as follows:—For 1 ton, 15s.; 2 tons, 30s. per ton; 3 tons, 25s. per ton; 4 tons, 22s. per ton; 5 tons, 21s. per ton; 6 tons, 20s. per ton; 7 tons, 19s. per ton; 8 tons, 18s. per ton; 9 tons, 18s. per ton; 10 tons, 18s. per ton. Less than 1 ton will be charged as 1 ton.

NEW PHOSPHATE DISCOVERIES IN TENNESSEE.

Eng. and Mining J., Oct. 31, 1896, 418.

Much interest has been created recently in middle Tennessee by the discovery of a new source of available phosphate rock in large quantities. This new source, says State Geologist James M. Safford, in the *American Geologist*, is one wholly different from that yielding the now well-known rock of Swan Creek. The rock of Swan Creek is Devonian; the one to be described is Trenton. That is a true rock itself; this is a residuum after the leaching of a rock. The rock is found in workable bodies over a wide area, including, it may be, 15 or 20 square miles of surface.

The centre of the present workings is in the town of Mount Pleasant, in Maury County. Here the phosphate is found, after stripping off the soil, in banks from 3 to 8 ft. in vertical thickness. Half a dozen companies are busily engaged in getting it out. The rock is light yellowish or grayish, of an open, spongy structure, and occurs in layers or plates of various thickness from 1 in. to 6 ins. or more. The material is easily quarried, picked out in blocks without blasting. All the stripping required is the removal of soil.

An analysis, made in Atlanta, by Mr. J. M. McCandless, gave: Calcium phosphate, 77.54; iron and alumina, 1.50; calcium carbonate, 6.83. Other analyses show calcium phosphate ranging from 60 per cent. to 81 per cent., the proportion of iron and alumina being usually within the limits required for a commercial product. The layers are evidently a residuum left after a natural leaching of certain highly phosphatic limestones from the long-continued action of atmospheric waters. There are four divisions in Tennessee of the limestones of the Trenton age. All of these are more or less phosphatic, but it is the Capital division which is the great source of the phosphate. Parts of this limestone show upon analysis from 15 per cent. to 25 per cent. of phosphate, the dark lines marking the lamination of the rock being especially rich.

BORNEO COAL.

Eng. and Mining J., Nov. 7, 1896, 436.

The influence of the coal mines of Borneo is beginning to be felt in Eastern markets, imports from that island at Singapore having increased in four years from 5,531 tons to 17,843 tons. As these imports compete chiefly with coal from India, the Indian Mining Association recently had assays made of three samples of Borneo coal, from the Sadong, Labuan, and Muara mines, the results being given as follows:—

	Sadong.	Labuan.	Muara.
Volatile matters.....	42.04	42.34	47.54
Fixed carbon.....	56.27	54.97	50.79
Ash.....	1.69	2.69	1.67
Total.....	100.00	100.00	100.00

These analyses, according to *Indian Engineering*, are quite equal to any of the best Bengal coal. The same authority says that Borneo coal is delivered at Singapore at 6.50 dols. to 7 dols., ex-ship, which is quite as low as Indian coal operators can do.

MINING IN JAPAN.

The *Japan Weekly Mail* states that, according to a native paper (the *Jiji*), the value of the mining output in Japan in 1892 amounted to 15,145,817 yen; in 1893 it was 16,385,817 yen; and in 1894, 20,199,874 yen. An increase of more than 40 per cent. in three years is not a bad record. The following table gives the value of the principal minerals obtained during the two years 1893 and 1894:—

	1893.	1894.
	Yen.	Yen.
Coal.....	6,837,809	9,385,155
Copper.....	4,903,515	5,967,917
Silver.....	2723,402	2,716,769
Gold.....	407,365	788,574
Iron.....	392,473	567,491

This table shows that the principal minerals of Japan are, but it would be erroneous to infer that other minerals are of small importance in Japan. That is not the case. In point of fact, gold, iron, and other mines have developed to a greater or less extent because of the facility for working them. Yet the output of kerosene increased from 200,000 yen in 1893 to 260,000 yen in the following year. Sulphur, plumbago, tin, lead, manganese, and so forth, all show a similar increase. It would not be an exaggeration to say that the supply of various ores is almost inexhaustible in Japan, and that the mining industry has not yet advanced beyond its threshold.

THE GERMAN CHEMICAL INDUSTRY.

Chemist and Druggist, Nov. 21, 1896, 759.

The German census returns recently published contain some interesting facts relative to the development of the chemical industry in Germany. There are at present in that country 102,923 persons whose principal active pursuit is connected with the chemical industry. The census of 1882 contained only 57,530 such, showing an increase of nearly 80 per cent. in 15 years, which represents a relatively much larger development when taking into account that labour-saving processes have greatly increased during that period. The greatest increase is in the branch relating to chemical, pharmaceutical, and photographic goods, where the numbers have risen from 18,561 to 36,428. The colour industry occupied 10,548 persons in 1882, and 19,418 in 1895; that of explosive substances, including matches, fireworks, &c., 9,067 in 1882, and 19,382 in 1895. Chemical manure-making and the treatment of waste products employed 6,932 people in 1882, and 12,661 in 1895. On the other hand, the number of pharmacists and persons engaged in pharmacy has only slightly increased, owing, of course, to the law limiting the number of concessions. Pharmacists in business on their own account numbered 4,829 in 1882, and 5,487 in 1895, while the total number of persons engaged in pharmacies, including principals, has increased from 12,422 to 15,634. The number of persons engaged as principals in the manufacture and trade in chemical, pharmaceutical, and photographic preparations has risen from 1,485 to 2,398; that similarly engaged in the colour industry from 823 to 909. On the other hand, the number of persons in this position in the chemical manure and waste products industries has declined from 1,735 to 1,387, and in explosives from 602 to 379, probably on account of the tendency, especially pronounced in these branches, to convert industrial undertakings into companies. In 1882 the entire German chemical industry occupied 42,422 manual labourers—viz., 37,501 males and 5,921 females. In 1895 it gave employment to 81,878 labourers, of which 67,782 were males and 14,096 females, the male element having thus increased by 81 per cent., the female by 138 per cent. Female labour is chiefly engaged

in explosives, match-making, colour-making, and next to that in the manufacture of pharmaceutical and photographic preparations. The general development of the German chemical industry is further shown by the fact that in 1882, 553,084 tons of crude material for use in that industry were imported from abroad, and in 1895, 1,326,160 tons, the export of chemical goods having increased during that period from 315,393 tons, worth 227,000,000 m., to 510,322 tons, worth 302,000,000 m.

THE ALCOHOL QUESTION.

Chemist and Druggist, Nov. 21, 1896, 740.

In the course of the discussion last week on the proposed new law regulating the sale of alcohol, the Senate fixed the duties on acetic acid of chemical origin manufactured in France, as follows:—(1.) Acetic acid, or dilutions of acetic acid containing 8 per cent. of acid and below, 10 fr.; 9 to 12 per cent. of acid, 15 fr.; 13 to 16 per cent. of acid, 20 fr.; 17 to 30 per cent. of acid, 37 fr.; more than 40 per cent. of acid will pay 105 fr. (2.) Crystallised acetic acid in a solid state will pay 125 fr. per 100 kilos. The same duties will be charged independently of Custom-house duties on acetic acids, dilutions of acetic acid, and crystallised acetic acid imported from abroad.

BOARD OF TRADE NOTICES.

CARRIAGE OF LIQUID AMMONIA ON BOARD SHIP.

The Board of Trade are advised that both the aqueous solution of ammonia and ammoniacal gas compressed into liquid form should be classed as dangerous goods, not only on account of the danger of explosion involved when they are contained in vessels not sufficiently strong to withstand the pressure which may be produced by a rise in temperature, but also on account of the highly dangerous nature of the gas.

The following precautions should be adopted when either of these liquids is carried on board ship:—

It should only be packed in iron vessels which have been carefully tested up to a pressure of 675 lb. per sq. in., and should be stored in a part of the ship beyond the influence of any heat from boilers or furnaces, and remote from the living quarters.

Ammonia solution of a specific gravity of 0.959 and upwards is exempted from the operation of the above instruction.

METHYLATED SPIRIT.

The surveyors are informed that the carriage of methylated spirit, or other similar inflammable liquid, as cargo on board emigrant ships is prohibited, and that no vessel having such spirit or other inflammable liquid on board as portion of her cargo should be allowed to clear under the Passengers Acts.

In the case of vessels which do not require to be cleared under the Passengers Acts, and which do not carry explosives, the following conditions should be observed if methylated spirit is carried below the weather deck:—

(a.) The spirit should be in substantial iron drums properly closed and secured.

(b.) The drums should be placed (and securely fastened to prevent violent movement) in a compartment by themselves, so constructed that, in the event of a fire, the burning spirit could not run out and spread over the vessel. With this view, the compartment (which should be of the character of the depots contemplated by the Inflammable Liquids Bill of 1891) should be proof against escape of liquid, whether burning or otherwise, and this condition would perhaps be best satisfied by means of an iron tank to be entered only from above.

(c.) The compartment should not be entered with naked lights, but only with safety lamps.

The volatile character of the methylated spirit, and the fact of its being a liquid, render it most necessary that some such provision should be made against what might otherwise be the very serious consequences of a leaky drum.

USE AND STOWAGE ON BOARD SHIP OF OILED MATERIALS.

The attention of the Board of Trade has been called to the danger arising from materials which have been dressed or soaked with oils, either raw or boiled, such as oiled clothing, oiled silk or cotton goods, and oiled paper, &c., whether in the piece or used for packing purposes.

The Board have reason to believe that materials which have been so treated are liable to spontaneous combustion, more especially in newly manufactured goods that have been insufficiently dried.

The Board of Trade think it desirable to inform all persons interested, that it is very important that cases containing oiled goods intended for exportation as merchandise, should be perforated or otherwise ventilated, and should be distinctly and conspicuously marked at full length in English, as required by section 146 of the Merchant Shipping Act, 1894.

When oiled materials are used for packing purposes great care should be exercised that they have first been properly dried, and also that the various folds do not overlap to such an extent as to bring several thicknesses of the material together.

On board ship, when oiled goods are carried under deck, care should be taken that they are stowed in a cool place, and in such a position that they can be readily got at.

SHIPMENT OF SULPHIDE OF SODIUM AND SULPHIDE OF POTASSIUM.

The attention of the Board of Trade has recently been called to a case of fire on board a steamship which is attributed to spontaneous combustion of sulphide of sodium forming part of her cargo.

The Board are advised that the chemical in question, as well as sulphide of potassium, is very liable, under certain conditions, to spontaneous combustion; and therefore caution shipowners and shipmasters against the dangers attending the stowage of either of them on board ship below the weather deck.

BOARD OF TRADE RETURNS.

Monthly Patent List.

* The dates given are the dates of the Official Journals in which acceptances of the Complete Specifications are advertised. Complete Specifications thus advertised as accepted are open to inspection at the Patent Office immediately, and to opposition within two months of the said dates.

I.—PLANT, APPARATUS, AND MACHINERY.

APPLICATIONS.

23,137. H. Booth. Improvements in filters for extracting oily matter from the feed-water supply of steam generators or the like. Oct. 19.

23,140. S. Mycock and F. C. Carter. Improvements in valves for controlling the flow of fluids. Oct. 19.

23,189. A. S. Barham and L. de Wittenbach. Improvements in apparatus for sterilising milk and other liquids. Oct. 19.

23,379. H. F. Stanley and The Farrington Works, Lim. Improvements in apparatus for refrigerating air and other gases. Oct. 21.

23,401. H. Desmarest. Improvements in refrigerating apparatus. Oct. 21.

23,723. T. C. Taylor and J. E. Tolson. Improvements in retorts for carbonising machines. Oct. 26.

23,792. R. Thiel. Improvements in or relating to closing device for receptacles for sterilising. Complete Specification. Oct. 26.

23,991. L. Sterne.—From The De La Vergne Refrigerating Machine Co. Improvements in refrigerating and ice-making apparatus. Complete Specification. Oct. 28.

24,405. R. M. McDougall. Improvements in the packing of the tubes in the rectifiers of Coffey's distilling apparatus. Nov. 2.

24,559. A. Helzel. Improvements in muffle furnaces. Nov. 3.

24,755. A. McQueen. Pressure gauge or indicator and safety valve for liquids and gases. Nov. 5.

24,850. J. T. Pearson. Improvements in the method of and apparatus for crushing steel and other hard substances. Nov. 6.

24,921. A. McDonadd. Improvements in retorts or vulcanisers. Nov. 6.

25,031. P. Funfak. Improvements in vessels for holding corrosive substances or the like. Complete Specification. Nov. 7.

25,250. W. E. Pedley. See Class X.

25,612. C. G. J. Moller. Improvements in apparatus for drying granular and other material. Nov. 13.

25,643. M. H. Smith. Improved apparatus for cooling purposes and for diffusing heat. Nov. 14.

COMPLETE SPECIFICATIONS ACCEPTED.*

1895.

20,292. S. S. Bromhead.—From C. Dicker. Distilling apparatus. Oct. 28.

22,920. W. E. Heys.—From J. Hundhausen. Method and apparatus for separating insoluble substance from liquids. Nov. 4.

22,924. W. E. Heys.—From J. Hundhausen. Method and apparatus for drying sensitive substances. Nov. 4.

24,943. T. B. Jones. Apparatus for filtering sewage and other liquids. Nov. 18.

25,049. D. A. Peniakoff. Rotatory apparatus for calcining substances. Nov. 18.

23,665A. L. Mond. Apparatus for treating solid and pasty substances with gases at elevated temperatures. Oct. 28.

1896.

75. W. W. R. Warn and L. F. King. Calcium carbide gas generators. Nov. 4.

17,408. H. Hirzel and R. Hoffmann. Apparatus for mixing and roasting materials of approximately equal specific gravity, and for separating materials of different specific gravity. Oct. 28.

17,821. T. B. Booth and A. Robinson. Apparatus for carbonating liquids. Nov. 11.

18,287. W. M. Fowler. Clarifying liquids. Nov. 4.

18,383. J. F. Stephenson. Apparatus for automatically removing solid matter from water or other liquids. Nov. 11.

19,761. W. R. Lake.—From A. Schwabe. Method of and apparatus for maintaining a uniform temperature in laboratory ovens, incubators, drying rooms, and the like. Oct. 28.

II.—FUEL, GAS, AND LIGHT.

APPLICATIONS.

23,147. W. J. Mackenzie. Improvements in apparatus for generating acetylene gas. Oct. 19.

23,233. C. S. Fletcher. "Fletcher's patent coke oven" for the reduction of the percentage of sulphur in coke. Oct. 20.

23,289. C. F. J. B. Becherel. Improvements in or relating to apparatus for the manufacture of acetylene gas. Filed Oct. 20. Date applied for June 27, being date of application in Belgium.

23,290. C. F. J. B. Becherel. Improvements in or relating to apparatus for the manufacture of acetylene gas. Oct. 20.

23,454. F. G. Bartlett. An improvement relating to burners for incandescent gas lighting. Complete Specification. Oct. 22.

23,483. F. B. Grundy and J. Moeller. Improvements in the manufacture of appliances for effecting self-lighting of gas. Oct. 22.

23,591. G. Trouve. Improvements in apparatus for producing and storing acetylene gas. Complete Specification. Filed Oct. 23. Date applied for April 14, 1896, being date of application in France.

23,592. G. Trouve. An acetylene lamp. Complete Specification. Filed Oct. 23. Date applied for May 11, 1896, being date of application in France.

23,595. E. Theisen. Improvements in purifying gases or vapours and gaining by-products therefrom, and in subjecting gases or vapours to the action of solid or liquid substances, and the converse by means of centrifugal action, and apparatus therefor. Complete Specification. Oct. 23.

23,669. H. E. Oving. Improved process and apparatus for the production and treatment of acetylene gas. Oct. 24.

23,670. H. E. Oving. Improvements in or relating to the treatment of acetylene or other gas for lighting, heating, or other purposes. Oct. 24.

23,701. H. Lane and B. T. L. Thomson. Improvements in the production of gas from petroleum and heavy oils for lighting and heating purposes, and in apparatus therefor. Oct. 24.

23,752. W. J. Mackenzie. Improvements in apparatus for generating acetylene gas. Oct. 26.

23,812. R. Haddan.—From H. Colberg. Improved apparatus for the automatic production of acetylene gas. Complete Specification. Oct. 26.

24,064. S. H. Crocker. Improvements in mantles for incandescent light. Oct. 28.

24,120. A. J. Boulton.—From A. Vandenbergh and A. Gardener. Improvements in or relating to the production of acetylene gas. Oct. 29.

24,208. D. M. Hughes. Improvements in incandescence burners adapted for consuming oil-gas. Oct. 30.

24,274. R. Turr. Improvements in apparatus for the production and combustion of acetylene gas. Complete Specification. Oct. 30.

24,344. H. V. R. Reed. Improvements in means for charging bottles and other vessels with compressed gases. Oct. 31.

24,378. G. Severac. Improvements in acetylene gas lamps and generators. Oct. 31.

24,411. F. S. Cripps. Improvements in the manufacture of illuminating gas. Nov. 2.

24,414. A. J. Smith and A. G. Smith. An improved automatic acetylene gas generator. Nov. 2.

24,440. P. de Resener and H. L. A. Luchaire. Improvements in apparatus for the manufacture of acetylene. Filed Nov. 2. Date applied for June 8, 1896, being date of application in France.

24,558. H. H. Lake.—From V. Hanotier and G. Hostelet. Improvements in lamps adapted for producing and burning acetylene gas. Nov. 3.

24,611. A. Kay. Improvements in portable apparatus for generating and storing acetylene gas. Nov. 4.

24,809. A. Schoenemann. Improvements in drying peat. Complete Specification. Nov. 5.

25,194. J. Byrom. Improvements in apparatus and valves for the generation and storage of acetylene gas. Nov. 10.

25,224. I. N. V. Bablon. Improvements in the production of acetylene gas and in apparatus therefor. Nov. 10.

25,236. E. Chesney, L. Pillion, and C. Bertolus. Improvements in apparatus for automatically producing and storing acetylene. Nov. 10. Date applied for May 9, 1896, being date of application in France.

25,339. T. B. Younger. Improvements relating to the manufacture of gas and coke. Nov. 11.

25,488. A. Fournier. Improved apparatus for the production of acetylene gas. Nov. 12.

25,498. A. I. Van Vriesland. Improved process and apparatus for producing gas or vapour from air and liquid hydrocarbons. Complete Specification. Nov. 13.

25,695. V. R. Lewes. Improvements in the manufacture of illuminating gas. Nov. 14.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

22,915. R. F. Strong. Manufacture of coal briquettes. Nov. 4.

23,051. O. Heimann. New process for making porous coke. Oct. 28.

23,436. J. Y. Johnson.—From The Badische Anilin and Soda Fabrik. Apparatus for refining crude petroleum and analogous oils by means of fuming sulphuric acid. Nov. 18.

23,639. T. Birnbaum. Apparatus for burning illuminating gas. Oct. 28.

24,689. C. J. Yarnold. Manufacture of ozone, and apparatus therefor. Nov. 11.

24,381. L. Denayrouze. Method and apparatus for charging air with combustible matter and applying it for illuminating. Nov. 18.

24,384. S. Cutler. Improved oil atomiser for gas carburetters. Oct. 28.

24,505. A. Taylor and W. S. Taylor. Mantles for incandescent gas lighting. Nov. 11.

1896.

1750. J. C. Mewburn.—From La Société Anonyme du Combustible. Manufacture of fuel briquettes or blocks. Nov. 11.

5336. R. Lavender and W. Tice. Appliances for increasing the illuminating power of gas under combustion. Nov. 11.

12,628. A. Bryce. A universal fuel injector. Nov. 18.

14,009. E. Fatham. Means for obtaining light and heat. Nov. 18.

14,213. A. Peugeot. A new system of air carburetter. Nov. 18.

16,541. M. Ekenberg. Manufacture of solidified petroleum. Oct. 28.

16,735. S. Marcus. Burners for gasifying and burning hydrocarbons, chiefly designed for the production of light by incandescence. Oct. 28.

19,957. H. Wellstein. Process of manufacturing mantles for incandescent burners. Nov. 4.

19,973. P. Bode. Incandescent gas burners. Oct. 28.

20,602. W. B. Rickman.—From J. Pintsh. Apparatus for the production of acetylene gas. Nov. 4.

20,903. V. Sardi. Apparatus for the manufacture of acetylene gas. Oct. 28.

21,267. G. Lowenberg. Composition to be used in the manufacture of glow bodies for incandescent lamps. Nov. 11.

21,468. S. Kon. Generators for acetylene gas. Nov. 4.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

APPLICATION.

23,649. J. Meikle. Improvements in obtaining benzene, toluene, and other products from mineral oils and liquid tars. Oct. 24.

COMPLETE SPECIFICATION ACCEPTED.

1896.

8718. E. Morrice. Naphthalene. Nov. 11.

IV.—COLOURING MATTERS AND DYES.

APPLICATIONS.

23,175. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brüning. Manufacture of new violet mono-azo dyestuffs for wool dyeing a fast brown by oxidation with chrome. Oct. 19.

23,358. J. Grossmann. Improvements in the manufacture and preservation of white indigo. Oct. 21.

23,554. T. A. Myers. Improvements in the manufacture and packing of blue for laundry purposes, liquid dyes, and other liquids. Oct. 23.

24,134. S. Pitt.—From L. Cassella and Co. Introduction of a blue dyestuff suitable for dyeing wool. Oct. 29.

24,408. I. Levinstein and Levinstein, Lim. Production of a new colour base and of colouring matters therefrom. Nov. 2.

25,128. O. Imray.—From The Society of Chemical Industry in Basle. Manufacture of new colouring matters dyeing from blue-green to blue, and of new chloro-derivatives and sulphonic derivatives of benzoic aldehyde therefor. Complete Specification. Nov. 9.

25,269. J. F. Schillis and P. Teichmann. The crown liquid bluing. Nov. 10.

25,592. C. W. Anderson, H. Benjamin, and J. Mendess. An improved liquid compound for dyeing purposes, also applicable for detergent, purifying, and disinfecting purposes. Nov. 13.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

22,417. H. E. Newton.—From The Farbenfabriken vormals F. Bayer and Co. The manufacture or production of dyestuffs for cotton. Oct. 28.

21,194. G. B. Ellis.—From La Société Chimique des Usines du Rhone, anciennement G. P. Monnet et Cartier. Production of para-nitro-phenetol and ortho-nitro-toluene-para-sulphonic acid. Nov. 4.

1896.

2196. C. D. Abel.—From The Actien Gesellschaft für Anilin Fabrikation. Manufacture of direct-dyeing azo colouring matters. Nov. 18.

19,516. O. Imray.—From The Society of Chemical Industry in Basle. Manufacture of colouring matters of the group of the rhodamines and of rhodol. Oct. 28.

V.—TEXTILES, COTTON, WOOL, SILK, ETC.

APPLICATIONS.

23,259. H. K. Tompkins. Improvements in the manufacture of artificial silk. Oct. 20.

23,427. C. J. Dear. A machine relating to the decortication of ramie and other fibrous plants. Oct. 22.

23,693. T. Ferguson. A liquid for blueing and clearing yarns and cloth manufactured from flax, hemp, cotton, silk, ramie, and other fibres. Oct. 24.

25,362. V. Bona. Improvements in the manufacture of textile fabrics. Complete Specification. Nov. 11.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

22,183. G. E. Wright and W. Monk. Method and apparatus for cleansing and recovering grease and oil from cotton and other waste and wool. Nov. 18.

14,760. G. C. Dymond.—From Erste Deutsche Patent-Linolium-Fabrik. Improved calendering machine for the production of running linoleum with inlaid coloured strips. Oct. 28.

VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

APPLICATIONS.

23,635. E. Makin, jun. Improvements in connection with kiers and like vessels for bleaching, dyeing, and similarly treating textile materials, yarns, and fabrics. Oct. 24.

23,718. H. Bentley. Improvements in apparatus for scouring and dyeing hanks of yarn or fibrous material. Oct. 26.

23,741. A. Liebmann and W. Kerr. Improvements in the methods or means for mordanting yarns, threads, fabrics, and other materials composed of fibres having a vegetable origin. Oct. 26.

23,797. M. Beraud and A. Lantmann. Improvements in dyeing fabrics. Oct. 26.

24,628. E. Beutz and F. J. Farrell. New or improved methods of dyeing animal fibres in a manufactured, partly manufactured, or unmanufactured state. Nov. 4.

25,348. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brüning. A method of dyeing wool with mordant dyestuffs in a single bath. Nov. 11.

25,492. W. Watson and Co., Lim., and E. Beutz. A new or improved method of fixing on cotton fabrics basic oxy-azo colouring matters produced on the fibre. Nov. 12.

25,581. E. J. Stewart. Improvements in dyeing. Nov. 13.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

22,185. M. H. Smallwood. Apparatus for bleaching washing, dyeing, and drying yarn in the cop. Oct. 28.

23,466. G. White. An improvement in drying spot, random, or any other parti-coloured dyed yarns. Oct. 28.

1896.

1375. J. Berry. Printing waterproof fabrics and apparatus therefor. Nov. 11.

VII.—ACIDS, ALKALIS, AND SALTS.

APPLICATIONS.

23,245. J. Pattison. Improved ammoniacal compounds. Oct. 20.

23,389. M. Sandecki. A new process of extracting carbonate of zinc from calamines. Oct. 21.

23,391. J. W. Fox. An improvement in the treatment of brine for the manufacture of table salt. Oct. 21.

23,614. J. W. Weston and T. I. Weston. Improvements in the manufacture of salt from brine and in apparatus therefor. Oct. 23.

23,853. F. M. Spence, D. D. Spence, and A. Shearer. Improvements in the manufacture of alumina and carbonate of soda. Oct. 27.

24,573. C. Hoepfner. Production of chloride of zinc and chlorine. Nov. 3.

25,100. A. Schmidt. Process for purifying crude acetic acid. Complete Specification. Nov. 9.

25,273. T. J. Vick and C. C. Askew. Perfected table salt. Nov. 11.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

22,715. R. England. Concentration of sulphuric acid. Oct. 28.

22,765. F. G. Powell, A. Powell, M. E. W. Powell, and R. H. R. Powell. Manufacture of vinegar. Nov. 4.

1896.

75. W. W. R. Warn and L. F. King. See Class I.

17,488. A. Kumpfmüller and E. Schultgen. Evaporation and concentration of solutions of salts. Nov. 4.

20,598. J. A. Denther. Improvements in and relating to calcium carbide and the treatment of the same to form a uniform composition. Nov. 11.

VIII.—GLASS, POTTERY, AND ENAMELS.

APPLICATIONS.

23,402. H. H. Lake.—From J. E. Winzer. Improvements in and relating to the burning and enamelling of earthenware and porcelain goods in kilns or ovens. Oct. 21.

23,724. J. Morton. Improvements in the method of and means for manufacturing glazed bricks. Oct. 26.

23,725. J. Morton. A new or improved method of and means for manufacturing glazed bricks. Oct. 26.

23,814. W. H. Godwin and T. Pickerill. Improvements in slabbing tiles, mosaics, and other similar appliances. Complete Specification. Oct. 26.

23,863. G. Boulton. Improved method or process of treating decorated ceramic ware for obviating the passing of such ware through a hardening-on kiln. Oct. 27.

24,033. J. Jacques, W. E. McCalla, and J. Nicholson. Improvements in the manufacture of articles in glass, tile, pottery, metals, and like substances by a process for producing thereon letters, figures, or designs in permanent colours. Oct. 28.

24,095. J. W. Knights. An improved method of making coloured tiles for floors or building purposes. Oct. 29.

24,249. J. Aynsley. Improved means for preventing the clinking or cracking of pottery ware in course of firing. Oct. 30.

25,326. A. J. Boulton.—From P. A. J. Gasse. Improvements in or relating to the decorating of earthenware, china, glass, tiles, bricks, and the like. Nov. 11.

25,665. J. Duckett and Son, Lim., J. Duckett, and J. W. Bullock. Improvements in the construction of muffled and semi-muffled kilns for burning bisquit and glazed ware. Nov. 14.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

22,054. J. Gordon. Glazing bricks, tiles, and other surfaces. Oct. 28.

24,286. A. J. Boulton.—From La Société Anonyme Belge pour la Fabrik des Emaux artistiques. Manufacture of glass. Nov. 4.

24,907. J. Phillips. See Class IX.

1896.

177. The Worcester Royal Porcelain Company, Lim., and E. P. Evans, and C. F. Binns. Manufacture of plates and other similar articles of pottery or earthenware. Nov. 4.

19,123. H. Knutze. Improved printing process for producing metallic decorations on earthenware, glass, and the like. Nov. 11.

21,762. D. Laffan, G. Moore, and T. J. Glynn. Apparatus for blowing or forming bottles and other glassware. Nov. 18.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

APPLICATIONS.

23,244. L. A. Smart and H. Robertson. Improvements in cement compositions for application in steel and iron ships and otherwise. Oct. 20.

23,360. R. Walker. Improvements in the manufacture of artificial stone blocks and building concrete walls therewith. Oct. 21.

24,242. A. Clery. Improvements in the manufacture of artificial stone. Complete Specification. Oct. 30.

24,711. R. Hunter. Improvements in the manufacture of finely pulverised substances for use in the production of Portland cement, pigments, and the like. Nov. 5.

24,902. A. Gries. Improvements in and relating to the production of slabs or such like for building and other purposes. Complete Specification. Nov. 6.

25,103. J. E. Whiting. Improvements in the processes for preserving timber and other organic products or substances by subjection to hot compressed air. Nov. 9.

25,132. S. W. Margetts and J. Cuthbert. An improved machine for grinding cement, clinker, and other hard substances. Nov. 9.

25,292. C. Craig and G. K. Craig. Improved forms of building blocks and method of using same. Nov. 11.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

23,773. M. M. Dessau. Paving blocks and slabs. Nov. 18.

24,907. J. Phillips. Continuous kilns for burning bricks, tiles, terra-cotta, lime, &c. Nov. 4.

1896.

759. G. R. Hilslop. Apparatus for revivifying spent limes, and for calcining cements and ores, or like materials. Nov. 18.

17,830. J. Foster. Construction of kilns for burning limestone, cement, and other similar material. Oct. 28.

X.—METALLURGY, MINING, ETC.

APPLICATIONS.

23,275. E. B. Parnell, A. Smith, and C. E. Monkhouse. Improvements in or relating to the treatment of ores and in apparatus therefor. Oct. 20.

23,470. B. E. Chaster. Improvements in extracting gold and platinum from ores or substances containing same. Oct. 22.

23,597. B. H. Thwaite and F. L. Gardner. Improvements in the method of working iron blast furnaces so as to utilise the gases evolved for producing motive power. Oct. 23.

23,788. H. E. Fry and N. G. Mackney. Improvements in the treatment of slags and ores containing zinc. Oct. 26.

23,817. B. Meyer. Improvements in the treatment of weldable iron. Complete Specification. Oct. 26.

23,836. G. A. Dick. Improvements in means or apparatus employed in the manufacture of wire rods or bars from various copper alloys and other metals. Oct. 27.

23,954. J. Y. Johnson.—From J. J. Deeble. Improvements in apparatus for use in the extraction of gold from auriferous material by the aid of chemical solvents. Complete Specification. Oct. 27.

23,958. G. W. Petersson. Process of manufacturing briquettes of iron ore or other iron compounds and briquettes thus made. Complete Specification. Filed Oct. 27. Date applied for March 27, 1896, being date of application in Sweden.

24,053. S. O. Cowper-Coles. Improvements in or connected with means for separating gold or other metals from solutions thereof. Oct. 28.

24,233. S. Neffgen. Improvements relating to processes and materials for treating poor iron and other ores and residues previous to the extraction of metal in the furnace. Oct. 30.

24,243. G. J. Atkins. Improvements in the treatment of ores, tailings, slimes, sands, and the like for the separation of metal therefrom. Oct. 30.

24,244. G. J. Atkins. Improvements in the recovery of metals from solutions of their salts by substitution and precipitation. Oct. 30.

24,417. B. C. Molloy. Improvements in extracting gold and silver from ores and compounds. Nov. 2.

24,657. R. F. Strong. Improvements in the treatment of ores for the production of iron, steel, and other metals. Nov. 4.

24,673. C. Jennings.—From A. F. Crosse. An improvement in the recovery of gold and silver from cyanide solutions containing the same. Nov. 4.

24,703. R. A. Hadfield. Improvements in the manufacture of iron alloys. Nov. 4.

24,705. R. A. Hadfield. Improvements in the manufacture or production of metallic alloys. Nov. 4.

25,045. J. R. Vellacott. Improved process for preventing any desired portions of iron or mild steel articles from being carbonised while the whole article is exposed to the action of carbonising agents while hot. Nov. 7.

25,133. A. Macdonald. See Class XIII.

25,250. W. E. Pedley. Improvements in apparatus for subjecting ores or other matters to heat or to the action of gases or liquids. Nov. 10.

25,375. S. O. Cowper-Coles. Improvements in the recovery of zinc, or of zinc and other metals, from zinc ores. Nov. 11.

25,461. W. P. Thompson.—From La Société Civile d'Etudes du Syndicat de l'Acier Gerard. Improvements in the manufacture of steel. Nov. 12.

25,462. W. P. Thompson.—From La Société Civile d'Etudes du Syndicat de l'Acier Gerard. Improvements in the pulverisation of metals with a view to the manufacture of steel and for other purposes. Nov. 12.

25,611. H. Maxim. An improved method and apparatus more especially intended for manufacturing calcium carbide and for the reduction of metals from their oxides. Nov. 13.

25,721. H. H. Lake.—From M. E. Waldstein. Improvements relating to the extraction of metals from their ores. Nov. 14.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

14,783. E. A. Ashcroft. Process for the treatment of metalliferous ores and products. Nov. 11.

19,784. J. Jones. A twyer for the better distribution of blast in blast furnaces and cupolas. Oct. 28.

22,092. C. Mason. Process for the prevention of articles made of suitable metals or alloys rusting after they are electro-plated. Nov. 18.

22,137. W. Woolf and J. Andrews. New or improved metallic alloy, and process for producing same. Oct. 28.

22,727. J. Gjers. Manufacture of cast steel and homogeneous iron. Nov. 18.

23,045. J. A. Kendall. Manufacture of sodium and potassium. Oct. 28.

23,543. T. Parker and J. Pullman. Process for treating sulphide ores containing zinc and other metals. Oct. 14.

23,665. I. Mond. Apparatus for treating nickel ores, and other materials containing nickel, with carbon monoxide, partly applicable to other purposes. Nov. 11.

1896.

123. J. Giers. Furnaces for the manufacture of cast steel and homogeneous iron. Nov. 11.

549. W. Blackmore. The treatment of antimonial and arsenical ores, materials, or furnace products containing gold, silver, or platinum. Nov. 18.

19,883. E. Fischer and C. G. Penney. Apparatus for extracting metals. Nov. 11.

22,715. J. W. Clarke. Amalgamating apparatus for extracting gold and silver from their ores. Nov. 4.

XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

APPLICATIONS.

23,258. B. E. Preston and C. Simkins. Improvements in primary electric batteries. Oct. 20.

23,663. P. Garuti and R. Pompili. New and useful improvements in the apparatus for the production of oxygen and hydrogen by electrolysis (System Garuti). Complete Specification. Oct. 24.

23,827. E. W. Bonson. Improvements in and connected with electrical storage batteries. Oct. 27.

23,868. L. Honig. Insulating compound. Complete Specification. Oct. 27.

24,019. L. J. H. Rochatte. Improvement relating to electric batteries. Filed Oct. 28. Date applied for April 21, 1896, being date of application in France.

24,473. H. Leitner. Improvements in and connected with primary and secondary galvanic elements. Nov. 2.

25,036. J. L. Dobell. Improvements in or connected with electric batteries. Nov. 7.

25,360. F. H. Snyder. Improvements relating to the coating, covering, or amalgamating of metals with metals, and of other substances with metals, and other materials by the aid of electricity, and to apparatus therefor. Complete Specification. Nov. 11.

25,365. H. Woodward. An improved electrode for secondary batteries. Nov. 11.

25,601. J. M. Moffat. Improvements in the cells or boxes of electric batteries. Nov. 13.

25,631. T. Parker. Improvements in the means employed in the electrolytic production of the chlorates of sodium and potassium. Nov. 14.

25,701. J. H. May and F. King. Improvements in or connected with secondary batteries. Nov. 14.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

20,542. G. Bell and G. W. Bell. Apparatus for the electrolytic decomposition of brine. Nov. 4.

22,142. P. Falle. Improved electric battery. Nov. 11.

22,233. M. Engl and F. Wüste. Improvements in accumulators and their electrode plates, partly applicable to primary batteries. Nov. 18.

23,097. R. Heathfield and W. S. Rawson. Improvements connected with the electrical deposition of zinc. Nov. 11.

1896.

557. R. Collins and F. Cogan. Electric batteries. Nov. 18.

1144. W. Heraeus. Electrodes for electrolytical purposes. Oct. 28.

12,250. C. Marschner. Plates for secondary galvanic batteries and a method of producing the same. Oct. 28.

15,129. F. W. Golby.—From O. Arlt. A process and apparatus for effecting electrolysis. Oct. 28.

19,301. A. Preiss. Storage batteries. Oct. 28.

20,505. H. Murray.—From R. J. W. Grindle. Electrodes for secondary voltaic batteries. Nov. 11.

20,600. J. A. Deuther. Electrodes. Nov. 11.

20,601. J. A. Deuther. Electric furnaces. Nov. 11.

XII.—FATS, OILS, AND SOAP.

APPLICATIONS.

18,589A. J. Hargreaves and R. Armstrong. Improvements in the manufacture of soap and in the method of obtaining glycerin therefrom. Nov. 10. Date claimed Aug. 22, 1896.

23,216. P. Vachey and J. G. D. de Miomandre. Apparatus for extracting by volatile or other solvents vegetable and animal fats and oils, vegetable, mineral, and animal waxes, tannins, pharmaceutical products, and tinctures, balsams, and resinous products, gums, and all direct essences of whatever kind. Oct. 19.

23,324. G. R. Redgrave. An improved process of oxidising oils. Oct. 21.

24,090. T. H. Bateman. A new or improved liquid soap. Oct. 29.

24,727. F. L. Bartelt. Improved scap or washing compound. Nov. 5.

24,728. F. L. Bartelt. A caustic detergent. Nov. 5.

24,875. W. McDonnell. Improvements in or connected with and apparatus for the manufacture of margarine. Nov. 6.

24,909. G. W. Hansen. Improvements in and relating to the manufacture of waterproof dubbing for leather and leather goods. Complete Specification. Nov. 6.

25,050. C. Bauer. Improvements in and relating to soap and other articles. Nov. 9.

25,472. J. Davidson. Improvements in the manufacture of fatty matter from certain animal tissues. Complete Specification. Nov. 12.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

22,183. G. E. Wright and W. Monk. See Class V.

18,940. F. Sahlfeld. A process of obtaining sebacic acid from wool or felling grease. Oct. 28.

XIII.—PAINTS, PIGMENTS, VARNISHES, RESINS, INDIA-RUBBER, Etc.

APPLICATIONS.

23,216. P. Vachey and J. G. D. de Miomandre. See Class XII.

23,221. C. O. Weber. Improvements in the vulcanisation of india-rubber and gutta-percha. Oct. 20.

23,294. The Non-Corrosive Preserving and Fire-Resisting Paint Co., Ltd., F. White, and J. Thomson. Improved non-corrosive preserving and fire-resisting paint. Complete Specification. Oct. 20.

23,446. K. F. Lindstram. Lindstram's non-fouling composition for preserving and protecting wood, iron, and metallic substances under water. Oct. 22.

23,700. J. Speir. An improved preparation or composition suitable for use as a substitute for linoleum india-rubber, and analogous substances. Oct. 21.

23,716. H. H. Lake.—From G. Hermegnies. Improvements in the manufacture of zinc white. Oct. 24.

21,318. E. A. Longbottom. A new or improved compound for marking sheep. Oct. 31.

24,711. R. Hunter. See Class IX.

25,133. A. Maedonald. Improvements in the manufacture of white lead pigment and in the separation of metallic lead from lead sulphide. Complete Specification. Nov. 9.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

21,085. J. McGillivray. Preservative coating for metals. Oct. 28.

22,797. W. Howarth and A. Marchbank. A new or improved blacking. Oct. 28.

23,969. C. D. Ismay. Manufacture of white lead. Nov. 11.

XIV.—TANNING, LEATHER, GLUE, AND SIZE.

APPLICATIONS.

23,742. J. T. McQuinn. Improvements in and connected with tanning hides, skins, and the like. Oct. 26.

24,812. A. M. Clark.—From Les Fils de F. P. Heinrich. An improved tanning process. Nov. 5.

24,819. H. Meister. Improvements in the manufacture of glue and gelatin cakes. Nov. 5.

24,885. L. de Barville, J. F. Roulleau, and L. V. Rance-lant. The manufacture of a substitute for leather and the like, and apparatus for use therein. Nov. 6.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

16,865. H. Riches and W. Riches. A novel and quick process in preparing skins and hides and making them into buff or oil leather in less than 24 hours. Nov. 18.

23,291. W. Sander.—From L. Lessmann. Improvement to preserve sole leather and make it absolutely water-tight. Nov. 4.

1896.

289. J. Hudson. See Class XV.

XV.—AGRICULTURE AND MANURES, Etc.

APPLICATIONS.

24,776. O. Heymann and A. Nitsch. Process and apparatus for the drying and disintegration of super-phosphates. Complete Specification. Nov. 5.

24,879. T. Twynam. Improvements in the utilisation of blast-furnace slag for the production of compounds suitable for use in agriculture and for the treatment of sewage effluent. Nov. 6.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

22,160. W. Barclay. Process for the production of blood and slag manure. Nov. 11.

1896.

289. J. Hudson. A process for rendering waste leather soluble and applicable as a manure. Nov. 11.

XVI.—SUGARS, STARCHES, GUMS, Etc.

APPLICATIONS.

23,318. J. Grosse. Improvements in the granulation of crystallisable liquids, and especially of the by-products of sugar manufacture. Complete Specification. Oct. 20.

24,038. F. W. Golby.—From J. Hensel. See Class XVIII. A.

24,760. R. W. Macadam and W. W. Macadam. The extraction, recovery, and manufacture of the saccharine matters in cereals, malted or otherwise, with their subsequent use in medical, culinary, domestic, and any manufac-

turing purposes as a substitute for or in conjunction with dextrose, saccharose, levulose, and such sugars as are commonly called grape sugar. Nov. 5.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

22,859. A. Wohl. Extracting sugar from its solutions. Nov. 11.

1896.

1101. M. Sachs. An improved process for treating the by-products of sugar works and sugar refineries. Nov. 18.

XVII.—BREWING, WINES, SPIRITS, Etc.

APPLICATIONS.

23,326. S. H. Wright. An improved method of dealing with yeast and apparatus therefor. Oct. 21.

24,945. R. D. Bailey. The extraction of tannin and resins from hops for use in brewing beer. Nov. 7.

COMPLETE SPECIFICATIONS ACCEPTED.

1896.

14,501. A. Moller. Manufacture of sparkling wine and apparatus therefor. Nov. 4.

17,183. A. Lippke. Process for the preservation of beer. Nov. 4.

XVIII.—FOODS, SANITATION, Etc., AND DISINFECTANTS

APPLICATIONS.

A.—Foods.

23,126. W. P. Thorapson.—From Kietz and Co. An improved process for the manufacture of strengthening and flavouring food extracts. Oct. 19.

23,311. F. Faulkner. New or improved manufacture or production of a substance suitable for use as food. Oct. 20.

23,400. H. H. Lake.—From A. Astolfi and E. Brugnattelli. An improved alimentary substance. Complete Specification. Oct. 21.

23,785. W. Luplau. Improved apparatus for use in the aëration of milk, and for attachment to milk cans and the like receptacles. Oct. 26.

24,038. F. W. Golby.—From J. Hensel. Process for the production of a food of a high nutritive value from the molasses of raw beet-sugar. Complete Specification. Oct. 28.

24,195. G. Jackson. An improved method for preservation of fish. Oct. 30.

24,587. J. Garton, M. E. G. Finch-Hatton, and R. Garton. Improvements in the treatment of grain and the manufacture of foodstuffs therefrom. Nov. 3.

25,127. G. J. Epstein. Improvements in the manufacture or production of cocoa and chocolate. Nov. 9.

25,204. H. D. Perky. Machines for the reduction of cereals and other products to useful, artistic, and convenient forms for food. Complete Specification. Nov. 10.

25,205. H. D. Perky. Method and means for the reduction of grain to thread-like or shredded form, and for the disposition of the same in the manufacture of biscuit and other forms of bread. Complete Specification. Nov. 10.

B.—Sanitation.

23,676. S. de Petroff. A new or improved method for the treatment of town sewage refuse and the like, for the destruction of animalculæ and the production of a fertilising compound. Complete Specification. Oct. 24.

24,833. B. Walker. The Walker process for treating sewage sludge. Nov. 6.

25,708. B. H. Scheibler. New or improved apparatus for the carbonising of rags. Complete Specification. Nov. 11.

C.—Disinfectants.

24,410. E. Domergue. A composition for preserving vines and fruit trees from the attacks of insects. Nov. 2.

25,592. C. W. Anderson, H. Benjamin, and J. Mendess. See Class IV.

COMPLETE SPECIFICATIONS ACCEPTED.**A.—Foods.**

1895.

22,989. L. P. J. Revel and J. M. Campagne. An improved process for the preservation of meat, fish, and other animal substances, and the manufacture of foodstuffs therefrom. Nov. 11.

1896.

18,275. L. G. Fagersten and C. E. P. Korsell. Improved process of sterilising or pasteurising milk and cream. Nov. 18.

B.—Sanitation.

1895.

22,132. H. L. Doulton and R. Meldrum. Process and apparatus for purifying water. Nov. 4.

22,502. R. H. Reeves. Improved means and appliances for the treatment of sewage at precipitating and at outfall works. Nov. 18.

C.—Disinfectants.

1896.

20,246. H. Hiscott. The manufacture of an improved disinfectant or composition for antiseptic, disinfecting, sanitary, and other purposes. Nov. 4.

20,792. W. O. Quibell, T. O. Quibell, O. Quibell, and W. B. B. Quibell. Sheep-dip powder. Oct. 28.

XIX.—PAPER, PASTEBOARD, Etc.**APPLICATIONS.**

21,010. D. C. Simpson. A new or improved composition for treating paper, cardboard, wood, or other materials of a similar nature, to render such material waterproof, and the markings with writing inks thereon indelible. Oct. 28.

25,068. D. N. Bertram and J. Blaine. Improvements in and relating to the straining of pulp in paper-making and like machines. Nov. 9.

25,077. P. Willmot. A new or improved process of treating paper to produce a washable surface for temporary drawing, sketching, and the like. Nov. 9.

25,693. W. B. Leachman. Improvements in or connected with the finishing process in the manufacture of paper and in apparatus therefor. Nov. 14.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

22,625. A. Zimmermann.—From The Chemische Fabrik auf Actien vormals E. Schering. Manufacture of water- and grease-proof paper. Nov. 18.

24,275. T. A. Marshall.—From G. Smidth. Separating fibres from the waste liquors of paper-making machinery. Nov. 4.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES, AND EXTRACTS.**APPLICATIONS.**

23,216. P. Vauchey and J. G. D. de Miomandre. See Class XII.

23,879. J. F. F. von Mering. New therapeutic substance, benzyl-morphine. Oct. 27.

24,568. A. Maile. An improved process for the manufacture of artificial musk. Nov. 3.

24,799. H. E. Newton.—From The Farbenfabriken vormals F. Bayer and Co. Improvements in the production of a pharmaceutical compound. Nov. 5.

25,377. W. Bevan. Improvements in the manufacture of white arsenic. Nov. 11.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

24,517. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brüning. Manufacture of hydroxy phenacetate salicylate. Oct. 28.

1896.

816. E. Darkopf. An improved process of producing methylenedinitric acids from formaldehyde and tannin. Oct. 28.

21,026. W. L. Wise.—From The Chemische Fabrik von Heyden Gesellschaft mit beschränkter Haftung. Manufacture of saccharine. Nov. 11.

XXI.—PHOTOGRAPHY.**APPLICATIONS.**

24,555. J. Ewing and T. R. Watson. Improvements in and connected with photography. Nov. 3.

24,817. C. C. Balston. Chromo-photography. Nov. 5.

COMPLETE SPECIFICATIONS ACCEPTED.

1896.

371. A. M. Clark.—From Lembach and Schleicher. Photographic developers. Nov. 18.

20,080. A. C. Edwards. Means or apparatus employed in the manufacture of photographic films.

20,387. T. C. Marceau. Producing photographs in relief. Nov. 11.

XXII.—EXPLOSIVES, MATCHES, Etc.**APPLICATIONS.**

23,612. W. Hope. Improvements in gunpowders and other explosives. Oct. 23.

23,613. W. Hope. Improvements in pellets and grains of gunpowder of any kind. Oct. 23.

24,955. A. Brock. Improvements in the manufacture of pyrotechnic compounds. Oct. 28.

25,704. A. E. Pike and W. H. Thew. Improvements in and in the manufacture of explosives or explosive compounds. Nov. 14.

25,711. C. Mortier and H. A. Sandon. Improvements in the manufacture of gunpowder. Complete Specification. Nov. 14.

COMPLETE SPECIFICATION ACCEPTED.

1896.

22,120. F. A. Halsen and W. C. Savage. Smokeless gunpowder. Nov. 11.

PATENT UNCLASSIFIABLE.**COMPLETE SPECIFICATION ACCEPTED.**

1896.

24,163. L. Grote. Improved process of manufacture of mouldable mass from asbestos fibre or other fibrous material. Oct. 28.

THE JOURNAL OF THE Society of Chemical Industry: A MONTHLY RECORD

FOR ALL INTERESTED IN CHEMICAL MANUFACTURES.

No. 12.—VOL. XV.]

DECEMBER 31, 1896.

[Non-Members 30/- per annum; Members
21/- per Set of extra or back numbers;
Single Copies (Members only) 2/6.

The Society of Chemical Industry.

Past Presidents:

Sir H. E. Roscoe, LL.D., V.P.R.S.	1881—1882.
Sir Frederick Abel, Bart., D.C.L., F.R.S.	1882—1883.
Walter Weldou, F.R.S.	1883—1884.
Dr. W. H. Perkin, F.R.S.	1884—1885.
E. K. Muspratt	1885—1886.
David Howard	1886—1887.
Prof. James Dewar, F.R.S.	1887—1888.
Ludwig Mond, F.R.S.	1888—1889.
Sir Lowthian Bell, Bart., F.R.S.	1889—1890.
E. Rider Cook	1890—1891.
Prof. J. Emerson Reynolds, M.D., D.Sc., F.R.S.	1891—1892.
Sir John Evans, K.C.B., F.R.S.	1892—1893.
E. C. C. Stanford	1893—1894.
Dr. T. E. Thorpe, LL.D., F.R.S.	1894—1895.
Thomas Tyrer	1895—1896.

COUNCIL FOR YEAR ENDING JULY, 1897.

President: Dr. Edward Schunck, F.R.S.

Vice-Presidents:

Chas. Dreyfus.	E. C. C. Stanford.
Dr. A. Dupré, F.R.S.	G. N. Stoker.
Prof. A. K. Huntington.	Dr. T. E. Thorpe, F.R.S.
Boverton Redwood.	Prof. W. A. Tilden, F.R.S.
Sir H. E. Roscoe, F.R.S.	Thomas Tyrer.
A. Gordon Salamon.	

Ordinary Members of Council:

George Beilby.	C. C. Hutchinson.
R. Forbes Carpenter.	Ivan Leviustein.
R. Le Neve Foster.	J. S. McArthur.
Oscar Guttman.	B. E. R. Newlands.
Douglas Herman.	Sir Robert Pullar.
David Howard.	Wm. Thorp, B.Sc.

With the Chairmen and Secretaries of Sections.

Honorary Treasurer:

E. Rider Cook, East London Soapworks, Bow, E.

Honorary Foreign Secretary:

Ludwig Mond, F.R.S.

General Secretary: Charles G. Cresswell.

Offices: Palace Chambers, 9, Bridge Street, Westminster, S.W.

THE JOURNAL.

Publication Committee:

The President.

A. H. Allen.	C. Clarke Hutchinson.
G. H. Bailey, D.Sc., Ph.D.	Wm. Kellner, Ph.D.
Joseph Bernays, M.I.C.E.	J. Lewkowsch, Ph.D.
H. Brunner.	A. R. Ling.
A. C. Clandet.	Ludwig Mond, F.R.S.
E. Rider Cook.	B. E. R. Newlands.
Chas. Dreyfus.	John Pattinson.
Sir John Evans, K.C.B., F.R.S.	W. H. Perkin, Ph.D., F.R.S.
G. G. Henderson, D.Sc.	H. R. Procter.
John Heron.	Boverton Redwood.
D. B. Hewitt, M.D.	Walter F. Reid.
David Howard.	John Spiller.
Prof. J. J. Hummel.	William Thorp.
Prof. A. K. Huntington.	Thomas Tyrer.
F. Hurter, Ph.D.	Lewis T. Wright.

Editor:

Watson Smith, 34, Upper Park Road, Haverstock Hill, N.W.

NOTICES.

COLLECTIVE INDEX.

A collective index, embracing the whole Journal from the Proceedings of the First Annual General Meeting, 1881, to the close of 1895, is now in preparation, and will be ready shortly. It will contain both a subject-matter and authors' names portion, and will be a volume of about 500 pages, uniform in size with the Journal.

The prices will be as follows:—

To Members (see Rules 25 and 27) and Past Members (see Rule 30); Libraries, Corporations, and Exchanges on the Society's List.	Each copy 10s.
To Subscribers	12s. 6d.
To others.....	15s.

Notice is hereby given, for the information of members and advertisers, that the advertisement columns of this Journal have been contracted for by Messrs. EYRE and SPOTTISWOODE, the Society's printers and publishers, to whom all communications respecting them should be addressed. The circulation of the Journal is now more than 3,000 per month.

Members are reminded that the subscription of 25s. for 1897, payable on January 1st next, should be sent in good time to the Treasurer, in order to ensure continuity in the receipt of the Society's Journal. Any changes of address to appear in the new List of Members now in course of preparation, should reach the General Secretary not later than January 15th, 1897.

NEW YORK SECTION.

Change of Address.

The official address of the Hon. Local Secretary, Dr. H. Schweitzer, is changed from 159, Front Street, to 77, William Street, New York, U.S.A.

LIST OF MEMBERS ELECTED 23rd DECEMBER 1896.

Brothers, Wm., 16, Manchester Road, Bury, Lancashire, Chemical Manufacturer.
 Browne, Augustus F., South Metropolitan Gasworks, 155, Rotherhithe Street, S.E., Gas Engineer.
 Campbell, Albert J., Broad Street Avenue, E.C., Engineer.
 Carmichael, Herbert, Bureau of Mines, Victoria, British Columbia, Public Analyst and Assayer.
 Claflin, Alan, Littleton, Mass., U.S.A., Manufacturing Chemist.
 Clinch, Jno. W., Eartfield House, Douglas, Isle of Man, Brewer.
 Edwards, W. Buckland, 101, Leadenhall Street, E.C., Analyst.
 Hand, Daniel, Edison Lamp Works, Newark, N.J., U.S.A., Chemist.
 Hudson, Jos., Rawden Lodge, Headingley, Leeds, Dry-salter.
 Fishman, G. P., Success, Fence Houses, co. Durham, Colliery Chemist.
 McMaster, D., McMurray's Royal Paper Mills, Wandsworth, S.W., Manager.
 Mann, E. A., Fremantle, West Australia, Government Inspector of Explosives.
 Russell, Geo. H., c/o Thomson and Son, New Chester Road, Tranmere, Birkenhead, Chemist (Gum and Gelatine Works).
 Sedling, G. H. P., Anita, Citrus Co., Florida, U.S.A., Chemist.
 Souther, H., Department of Tests, Pope Manufacturing Co., Hartford, Conn., U.S.A., Chemical and Metallurgical Engineer.
 Statham, Noel, 21, Midland Street, Widnes, Engineer.
 Vincent, Jos. A., 309, Bullitt Building, Philadelphia, Pa., U.S.A., Mechanical Engineer.
 Weightman, Alf. T., c/o Chloride Electrical Storage Syndicate, Clifton Junction, near Manchester, Electro-Chemist.

CHANGES OF ADDRESS.

Akitt, Thos. (Mexico); Journals to Langbank, Renfrewshire.
 Ansell, G., 1 o South Kensington; 3, Cross Lane, St. Mary-at-Hill, E.C.
 Bayay, A. de, 1 o Melbourne; Foster's Brewery, Collingwood, Melbourne, Victoria.
 Beadle, C., 1 o London; 60, West Street, Erith; Journals as before.

"Berichte der Deutschen Chemischen Gesellschaft"; Journals to Prof. Dr. S. Gabriel, Reichstags-Ufer 211, Berlin, N.W.

Bishop, Fred., 1 o Linlithgow; c/o Burmah Oil Co., Rangoon, Burmah.
 Boothby, C., 1 o Vauxhall; 9, Tyndall Road, Leyton, E.
 Davis, F., 1 o Newington; 51, Imperial Buildings, Ludgate Circus, E.C.
 Devey, A. C., 1 o Paris; 43, Redcliffe Gardens, South Kensington, S.W.

DR. R. MESSEL IN THE CHAIR.

NOTES ON THE SPONTANEOUS OXIDATION OF ALUMINIUM IN CONTACT WITH MERCURY.

BY H. F. HUNT AND L. J. STEELE, A.I.E.E.

OUR attention was first drawn to this subject towards the end of March 1895, when we noticed that a piece of commercial aluminium which had been standing in dirty mercury for several days, became coated with a white substance of an extremely light and fragile nature.

Owing to the growing use of aluminium for industrial purposes, we consider the matter of sufficient interest to warrant our publishing the following results of our own observations; and in order to make this paper as complete as possible, we have added a summary of the chief facts which have hitherto been published, dealing with the influence of mercury on the spontaneous oxidation of aluminium.

We found that the formation of this peculiar white substance alluded to above could be made to occur more rapidly by vigorously rubbing the specimen after removing it from the mercury. The aluminium appears at first to be tarnished, and then becomes covered with a whitish substance. At edges or corners, and along scratches on the surface, this substance is denser and its growth more rapid than at other parts. Curious motions accompany the growth, and the fact of an inorganic substance visibly growing out of a homogeneous piece of metal greatly increased the interest of the phenomenon.

Below are the conditions under which we found the substance to form:—

1. By allowing the aluminium to stand on mercury, covered with a thick film of oxide. In this case the aluminium does not visibly amalgamate, and the white formation occurs on almost all parts of the metal, even where not directly in contact with the mercury.

2. By keeping the aluminium beneath dirty mercury. It was found on removal that the action was far weaker than in the previous case.

3. By standing the aluminium on distilled mercury. The white substance produced in this case was so slight as to be scarcely visible, whilst none at all was produced by keeping the aluminium submerged under distilled mercury.

4. By amalgamating the surface of the aluminium with mercury, in the presence of either potassium cyanide, or nitric or sulphuric or hydrochloric acid, or by the presence of sodium amalgam. The white concretions resulting from this amalgamated aluminium are thicker, but much more uniform in their growth, than those resulting by leaving the aluminium on a film of mercurous oxide, as described

above. But one does not get such curious motions from the amalgam as from aluminium which has stood on slightly oxidised mercury.

When examined under an $\frac{1}{8}$ -inch objective, this white substance is seen to consist of dendritic masses of an apparently homogeneous material. After a polished surface of aluminium has been in contact or rubbed with mercury and then allowed to oxidise for an hour, the surface when again cleaned is seen to be pitted when examined under the microscope. An examination of the piece of aluminium used in this experiment revealed very small traces of iron. This phenomenon has been obtained with as pure brands of aluminium as could be commercially obtained, but in these cases the action is far less vigorous.

The result of an analysis gave aluminium as the only metal present in this white material. It was found to be soluble in dilute acids before ignition, but after ignition to be insoluble even in concentrated mineral acids; at the same time it underwent a loss of weight compatible with that required in the conversion of $Al_2(OH)_6$ into Al_2O_3 (aluminium hydrate into aluminium oxide). We therefore concluded that the white substance was a hydrate, and not a mere oxide of aluminium.

One of our first experiments was to find out whether this aluminium hydrate would form under oil. Two or three different kinds of oils were tried, but in no case did the hydrate form under them.

In another experiment we lowered a piece of aluminium foil, previously rubbed with sodium amalgam, into a jar of moist oxygen, but no appreciable increase of oxidation was observed, compared with a similar experiment carried out in moist air.

On immersing a piece of amalgamated aluminium in water, we found that a very flocculent greyish sediment was formed. When dried, this sediment turned white and proved to have the same composition as the white hydrate of the previous experiments. During the formation of this grey deposit, which in some cases would continue for 24 hours or more, there was a continual evolution of hydrogen gas.

We find on referring to previous work on this subject that the phenomenon of the rapid oxidation of aluminium after being rubbed with mercury was first described by Carl Jehn and H. Hinze (Ber. der D. Chem. Gesell., Nov. 12, 1874). The authors of that paper describe accurately how in a few moments masses of white material make their appearance and grow to a height of about 3 mm. We have frequently obtained it 15 mm. and more in height. Its composition there is given as almost pure alumina, Al_2O_3 , and not the hydrate as found by us.

In Thorpe's Dictionary of Chemistry, we find it stated that pure aluminium combines with mercury, although not readily, when the metals are heated together in an inert gas such as carbonic anhydride. The two metals combine rapidly in presence of alkalis. The amalgam may also be prepared by electrolysis of mercuric nitrate, using a negative plate of aluminium dipping in mercury.

According to Hinze (D.P.J. 227, 277), this oxidation does not take place in dry air, and is due to galvanic action on the water. We ourselves are inclined to support this view that the action is electrical. Aluminium becomes covered with alumina when pressed against moist platinum, and we are now carrying out experiments on the effect of contact between aluminium and other metals. The fact of the hydrate forming more thickly at corners and edges, where the electrical resistance would be lowest, tends also to support the theory of the action being electrical. We have, indeed, obtained galvanometer deflections between the aluminium and the mercury, but we do not base much reliance on this fact, as it may possibly have been due to other causes.

The Ber. 1895, 28, 1323—1327 gives an account of the first practical application of amalgamated aluminium. It had then (1895) been known for some years that amalgamated aluminium rapidly decomposed water, but mention is made in that paper for the first time of how much this amalgam can be used as a neutral reducing agent; for instance, nitrobenzene has been very successfully reduced to aniline in aqueous alcoholic solution by this method.

The rapid corrosion of aluminium under certain circumstances has thrown some doubt on the successful use of this metal for industrial purposes. Several brands and alloys containing small percentages of manganese, titanium, German silver, &c., have been recommended as being capable of thoroughly withstanding all atmospheric conditions, but there is undoubtedly room for investigation here. Examples of the corrosion of commercial aluminium are common enough. As an instance we may quote an experiment of the Sydney University, where two shallow aluminium dishes $\frac{3}{4}$ in. thick were left exposed on a honsetop for 54 weeks. The surfaces corroded badly and the weight of the dishes increased by about 1 per cent., doubtless owing to the formation of hydrated oxide. Then again in the report issued last year on the Texas torpedo boats with aluminium fittings, we find it stated that wherever such fittings touched the salt water, holes were eaten through, and even those on deck began to crumble on account of the salt air. One of us was recently told by the surgeon at a hospital that some difficulty had been experienced in the use of aluminium splints, owing to a whitish film sometimes forming upon them. The physician had put this down to want of care on the part of his assistants, and did not suspect that the perchloride of mercury, used as an antiseptic, had any connection with it.

Both English and French navies have tried aluminium as a means of lightening their torpedo boats, but we fear the experiments were not altogether a success. In one instance an aluminium boat was chained to the same buoy as another boat plated with copper; the galvanic effect in this case was extraordinary. The English torpedo destroyer "Boxer" has had its aluminium torpedo tubes removed owing to their rapid corrosion. Numbers of other instances could be cited showing the deteriorating effect of salt water on aluminium; the French indeed have shown that the metal loses 4 per cent. per annum of its weight in salt water. Aluminium utensils are now coming into rather extensive use, notably in the French army, and not very much trouble has been experienced by corrosion, except where the articles have been washed in alkali or where the metal contained impurities. Aluminium, when quite pure and thoroughly homogeneous, is not nearly so liable to attack as that containing impurities such as sodium. Pure aluminium, on the other hand, is mechanically so much weaker than many of its alloys that consideration has to be taken as to whether the metal is required to resist stresses or to withstand corrosion.

DISCUSSION.

Mr. O. GUTTMANN wished to draw attention to a new experience resulting from the behaviour of aluminium which was *à propos* to the facts brought before them by the authors. A friend of his had recently used large aluminium vessels for the purpose of nitrating cellulose, and found that, although the metal was attacked by either sulphuric acid or nitric acid alone, it was not appreciably attacked by a mixture of the two acids, and had in fact stood the work with perfect success for the last three months.

Mr. R. TERVET drew attention to a remarkable effect produced upon a plate of aluminium when brought in contact with mercury in presence of a weak solution of silver nitrate and nitric acid. After about 12 hours' contact the aluminium swells enormously, and splits up into a hundred or more exceedingly thin plates, which gives the mass a laminated appearance. These thin plates form at the same time the boundaries of small lenticular-shaped cavities, from which a constant stream of gas issues so long as unoxidised aluminium remains. When once started the oxidation of the amalgamated aluminium proceeds as actively under distilled water as it does in the presence of the silver nitrate and nitric acid.

With regard to the case of oxidation, which was the subject of the paper, he might remark that it had been referred to earlier by other observers, and the most successful way of producing the effect was to place the piece of aluminium in a flat dish, cover with a strong solution of sulphate of zinc, and rub the aluminium with the mercury. The aluminium, after being washed and rapidly dried with a cloth, would oxidise rapidly and

become so hot as to be unbearable in the hand, while the growth of oxide would shoot out several inches in the course of three or four minutes.

The behaviour of aluminium with copper sulphate moistened with dilute sulphuric acid was interesting, but for some reason uncertain.

A MEMBER observed that some years ago he had used aluminium in the construction of electric batteries with precisely the same result. On rubbing the metal with corrosive sublimate, oxidation immediately took place, and so the use of aluminium for that purpose had to be abandoned.

Mr. O. HEHNER said that results similar to those obtained by the authors had been described in the *Chemical News* in or about the year 1878. In fact it had been discovered over and over again. The action of the aluminium amalgam was doubtless similar to the copper-zinc couple of Gladstone and Triebel, and, like the latter, it might be found to be practically applicable to various chemical reactions.

A MEMBER asked if the authors had proved that the white substance produced was a hydrate. It was stated in the paper that it was practically a hydrous oxide, but that there was not sufficient water present to hydrate the whole.

Mr. STEELE, in reply, said that he and his colleague were quite aware that work had been done on the subject before, but they having found that the action was accompanied by the phenomena stated in their paper, thought the matter of sufficient interest to bring before the Society. They had, with the aid of Mr. Julian Baker, carried out several analyses of the white substance, and the result led them, in every case, to believe that it was a hydrate.

Mr. O. HEHNER asked if they had determined the amount of water given off.

Mr. STEELE replied that some recent experiments of theirs had fully confirmed the view that the substance under consideration was a hydrate and not an oxide. Mr. Julian L. Baker, to whom they had sent samples for analysis, had reported that aluminium was the only metal present. Before ignition the substance was soluble in dilute hydrochloric acid, but afterwards it was insoluble in concentrated hydrochloric acid. As shown by the following figures, it lost during ignition an amount of water compatible with that required on the conversion of $Al_2(OH)_6$ into Al_2O_3 :—

(1.) 0.0898 gram. of substance, dried at $100^\circ C$, lost 0.0323 gram. when ignited over a blow-pipe flame in a platinum crucible. In this case the observed loss of water was 35.9 per cent., against the theoretical 34.6.

(2.) 0.0520 gram. of another sample, also dried at $100^\circ C$, lost 0.0199 gram., or 38.4 per cent., against the theoretical 34.6.

These numbers showed that they were dealing with hydrate of aluminium. Additional proof was afforded by the behaviour of the substance towards hydrochloric acid before and after ignition.

DR. C. A. KOHN IN THE CHAIR.

RESCUE APPARATUS FOR USE IN NOXIOUS ATMOSPHERES.

BY ARTHUR CAREY, M.S.C.

TOWARDS the end of last session I promised to read a paper before this Society on the results of some experiments conducted by the United Alkali Co., on the best practicable means of avoiding accidents from what is popularly known as "gassing;" or at any rate of preventing those accidents when they do occur from having fatal results.

Since that time, however, the ground has been largely cut from under my feet, in the first place by Mr. Herman who read a paper before this Section in April last on this same subject, and in the second by the publication of a very excellent article in the Chemical Trade Journal, of October 24th, which embodies most of the results I wished to lay before you.

All that is left for me to do this evening is to give you, by permission of the Directors of the United Alkali Co., an account of the steps taken by them to meet the clauses contained in the Special Rules for Chemical Works, issued by Her Majesty's Chief Inspector of Factories under clause 8 of the Factory and Workshops Act of 1891.

The clauses in these special rules bearing on this subject are the following:—

Clause No. 5. "Suitable respirators shall be provided for the use of the workers in places where poisonous gases or injurious dust may be inhaled."

Clause No. 9. "Respirators charged with moist oxide of iron or other suitable material shall be kept in accessible places ready for use in cases of emergency arising from H_2S or other poisonous gas."

These two clauses refer each to a definite use of a respirator; No. 5 to the use of a respirator during normal work; No. 9 to the use of a respirator in cases of emergency, and therefore only for short spaces of time.

Nearly two years ago the United Alkali Co. instructed Messrs. V. C. Driffield, Percy Bateson, J. Marsh, and myself to investigate the subject of respirators and rescue apparatus generally.

In accordance with the conditions of work in the United Alkali Co., our investigations were almost exclusively directed to emergency respirators and apparatus, as required under clause 9 of the special rules. But very naturally many of the facts bearing on emergency apparatus, bear equally on apparatus for use during normal work, and, as a matter of fact, we eventually came to the conclusion that with a very slight alteration (which I will explain later), the same apparatus is applicable to both cases.

In considering the question of the best emergency respirator or other apparatus to enable men to exist without injury in a noxious atmosphere, we found that there are three main points to be weighed:—

1. Safety.
2. Rapidity of adjustment.
3. Minimum interference with active exertion or powers of observation.

We further found that all appliances for this purpose may be classed under three heads:—

(A.) Those which purify the atmosphere by absorbing its noxious constituents.

(B.) Those which supply fresh air from outside.

(C.) Those which contain in themselves the oxygen necessary to maintain life.

Our early investigations were made almost entirely on appliances belonging to class (A). I will therefore deal with them first.

After a considerable number of inquiries and experiments, we selected as a temporary solution of the difficulty a modification of the "Zimmer respirator."

We were quite aware that this respirator was, for our purpose, not completely satisfactory, but we did not realise how far it was from approaching to the first "desideratum" of a respirator, *i.e.*, safety.

I personally did most of the experiments with this muzzle, and I made the very serious error of using chlorine as the "test gas." I failed to realise how important a part is played in the efficiency of a respirator by the relative affinity of the different gases for even the most powerful absorbents.

We tried various absorbents, and finally selected carefully ground charcoal saturated with caustic soda solution.

As a practical trial, I went into a Weldon B. P. Chamber, containing dense yellow chlorine (4—6 grs. per cub. ft.) wearing this respirator and a pair of goggles, and remained in for several minutes without inconvenience.

In our modification of the "Zimmer" respirator we abolished the outlet valve and the opening for the nose. We also made the respirator oval so as more closely to fit the face, and deepened the absorption chamber.

Shortly after this we made some experiments at the request of Mr. Richmond, Her Majesty's Inspector of Workshops and Factories with the "Tyndal fire helmet."

In this and in our later experiments we were assisted by Mr. Towers, of Widnes who, together with my assistant, Mr. J. Betney, performed most of the experiments.

The Tyndal fire helmets are fitted with an absorption chamber consisting of a tin cylinder 4 ins. long by $2\frac{1}{2}$ ins. diameter closed at each end by wire gauze.

The packing of this cylinder consists chiefly of cotton-wool. Part of the cotton-wool is saturated with glycerin, and there is also a thin layer of charcoal and another of lime.

Such an absorbent is absolutely valueless for any purpose but that of a dust and smoke filter, for which purpose it was originally designed.

As we could find no respirator on the market which gave any promise of being suitable for our purpose, we commenced to experiment on lines of our own.

We considered that the reason for our former failures was chiefly the small size of the purification chamber, and that granted a sufficiently large chamber, *i.e.*, granted sufficient time of contact, there was no reason why chemical absorbents should not completely remove all traces of such gases as H_2S and CO_2 .

We therefore made a series of experiments, starting with a large absorber and gradually decreasing the size, in order to determine the minimum dimensions compatible with efficiency.

We used in each case a number of different absorbents.

H_2S was our test gas, and was collected together with air in varying but known proportions in a gas holder of 6 cubic feet capacity. The gases in the holder were tested before and after each experiment; and were drawn through the purifier to be tested by means of a "Fletcher's bellows aspirator," in order to imitate, as nearly as possible, the intermittent character of ordinary respiration.

We also, as nearly as we could, aspirated the gases at about the rate of normal respiration, *viz.*, about one-third cubic foot per minute. The exit gases were tested by lead acetate paper, which was found to blacken in an atmosphere containing 0.01 per cent. H_2S by vol. We further found that a mouse placed in an atmosphere containing 0.1 per cent. H_2S by vol. became insensible in about six minutes, but recovered again in fresh air. In another experiment a mouse placed in an atmosphere containing about 0.05 per cent. H_2S showed no signs of distress after 30 minutes.

There is therefore no doubt that gas which will not blacken lead paper will not harm men.

The only two absorbents we found of any practical use were granulated soda lime and charcoal saturated with caustic soda. In the latter case we found, as would be expected, that the absorptive power increased with the fineness of the charcoal and with the per cent. of Na_2O contained in it.

We tried absorbers of the following dimensions:—

No. 1 with a capacity of 138 cb. ins.

" 2 " " 31 "

No. 3 with a capacity of 26 cb. ins.

" 4 " " 12½ "

The following table contains the results:—

Capacity of Absorber.	Description of Packing used.	Gas used.	Result.	
			Cubic feet aspirated before Paper blackened.	C. Ft. × (H ₂ S + CO ₂).
138	Charcoal passed through 1-inch mesh sieve, saturated with 30% Twad. caustic soda solution.	7 H ₂ S	3.75	26
		13.5 "	1.5	20
		14 "	A mouse became insensible at 3.5 cubic feet, but came round in fresh air.	49
138	Charcoal caught between 16 and 60 mesh sieves, containing 10% Na ₂ O.	8.5 "	"	76
138	Granulated soda lime.....	24.7 "	Not blackened at 12 cubic feet	296
31	Charcoal passed through 1-inch mesh sieve, saturated with 30% Twad. caustic solution.	14 "	Blackened at once.	
31	Charcoal caught between 16 and 60 mesh sieves, containing 10% Na ₂ O.	5 "	2.5	12
31	Charcoal caught between 30 and 40 mesh sieves, containing 20% Na ₂ O.	14 "	5	70
31	Granulated soda lime.....	7.5 "	9	67
26	Charcoal caught between 20 and 40 mesh sieve, containing 26% Na ₂ O.	21 "	3.5	73
26	Charcoal caught between 20 and 40 mesh sieve, containing 26% Na ₂ O.	15 CO ₂ 7 "	2.5	55
12.5	Packing used in Tyndal Fire Helmet.....	11.5 H ₂ S	Blackened at once.	
12.5	Charcoal passed through 1-inch mesh sieve, saturated with 30% Twad. caustic solution.	8 "	0.33	3
12.5	Charcoal caught between 20 and 30 mesh sieves, containing 20% Na ₂ O.	20.6 "	1	21
12.5	Granulated soda lime.....	8 "	Not blackened after 5 cubic feet, but the absorber rose to 400° F.	10

As is shown by the table, the gases used were not of a uniform strength, and in order to get roughly comparative figures I have in column four calculated all the results for a gas containing 1 per cent. H₂S by vol.

There does not appear to be much difference between the absorptive power of the granulated soda lime and the very finely-divided charcoal, caught between a 20 and a 60 mesh sieve and containing 26 per cent. Na₂O. We were led, however, to choose the charcoal because we found that, when hot, small quantities of caustic were carried over from the soda lime, and though, of course, this was not sufficient to be dangerous, it was decidedly unpleasant.

I must mention that the use of the very finely-divided charcoal containing a high percentage of Na₂O, was the idea of Mr. Towers, who prepared all we used in these experiments.

Figures 1 and 2 show the apparatus which was adopted by the United Alkali Co. as a result of these experiments. This apparatus is made by Mr. Towers and has been patented by him. It contains an absorption chamber with a capacity of 50 cubic inches.

The absorber is attached to a belt and is carried on the middle of the wearer's back.

Fig. 1.

Fig. 2.

The connection with the mouth is made by a flexible india-rubber tube passing over the shoulder and terminating in a mouth piece.

The mouthpiece is the design of Mr. Towers and has an automatic outlet and an inlet valve. A small nose clip is attached for the use of those who are not accustomed to breath exclusively through the mouth.

The belt carrying the absorber is made strong enough to carry a man, and is fitted with a strong iron ring for the rope, which should be invariably attached, except when either the man has an intricate path to follow while in the noxious atmosphere, or when there is no one outside to hold the free end.

This arrangement, the method of wearing which is shown in the accompanying photograph (Fig. 3), appears to us to combine speed of adjustment with freedom from danger of unnecessarily impeding the actions of the wearer.

Fig. 3.

We now come to the consideration of appliances belonging to class (B.), i.e., those which involve direct connection with the open air by a pipe, through which the fresh air is either drawn or pumped into the lungs of the wearer.

As we were dealing with emergency work, in which, as I have pointed out before, speed of adjustment is one of the first considerations, we came at once to the conclusion that any apparatus which involves pumping of air is out of the question. The presence of the pump involves also a more complicated apparatus, and one therefore more likely to get out of order. In addition to this, we found that a man can without much inconvenience draw his breath through as long a pipe as he can drag after him.

The well known "Denayrouze" apparatus is constructed on this principle. This apparatus consists simply of a length of india-rubber piping attached to the wearer by a stout leather belt, and carrying a mouthpiece connected with an inlet and an outlet valve. The apparatus is also supplied with a face piece to protect the eyes, and at the same time to close the nose by pinching it.

Fig. 4 is a photograph of a man wearing the apparatus we finally selected. It consists of a length (50—60 ft.) of india-rubber piping (with embedded wire), $\frac{3}{4}$ inch internal diameter, the weight of which is carried from the centre of the wearer's back by a stout leather belt fitted, as in the case of the respirator, with a stout iron ring.

The pipe from the belt to the mouth is of light flexible india-rubber, and terminates in one of Mr. Towers' mouthpieces.

As it is very rarely that in the United Alkali Co.'s works gases will be met which quickly attack the eyes, we discarded the cumbersome face piece and substituted for it a small nose-clip.

Fig. 4.

For use on the rare occasion when the eyes are likely to be attacked, the case in which the apparatus is carried contains a pair of goggles, which are very fairly efficient and very easily adjusted.

There are some obvious risks in the use of such an apparatus, as either the "Denayrouze" or the "safety pipe" I have described, and they are that through negligence, the free end of the pipe may be drawn after the wearer into the noxious atmosphere, that a kink or crack may occur in the pipe itself or the valves may get out of order.

To meet these difficulties there should be always two men on the job, one to rescue and one to look after the free end of the pipe. The pipe itself must be wired and the whole must be subjected to periodical and thorough examination.

There is still another risk, and that is, that if the atmosphere is thick and there are pillars or machinery about, a man may not take the same path out that he took in, and may get his pipe wound round an immovable obstacle.

This risk is one which can only be avoided by care on the part of the wearer, and cannot be otherwise guarded against.

In spite of these disadvantages, however, the use of an apparatus such as the "safety pipe" is absolutely necessary under certain conditions. For instance, when there is reason to suspect the absence of oxygen or the presence of some injurious gas which a respirator will not absorb.

There yet remain appliances of the 3rd class, i.e., those which contain within themselves the oxygen necessary for respiration.

For emergency work, where the apparatus may be years without use, we came to the conclusion that apparatus of this class is valueless.

Our investigations have led us to the conclusion that in all cases where there is no reason to suspect the absence of oxygen or the presence of gases not absorbed by caustic soda, such as CO, or oxides of nitrogen, a respirator such as that I have described, containing an absorption chamber of about 50 cubic inches capacity, and charged with finely-powdered charcoal containing about 26 per cent. Na_2O , is the most serviceable rescue appliance.

Where, however, there is reason to suspect the absence of oxygen or the presence of such gases as CO or oxides of

nitrogen, direct connection with the open air is essential, and the use of a "safety pipe" is necessary.

Earlier on in this paper I stated we had found that a very small alteration was necessary to make apparatus designed for rescue purposes suitable for normal work in places where either there is or may be quantities of noxious gases; such, for instance, as sewers, "Chance" carbonators, or vitriol chambers, all of which have to be entered occasionally for cleaning.

When men have to do severe physical work for any length of time they are bound to breathe, not only through the mouth, but through the nose also, and to meet this we have found it necessary to substitute for the mouthpiece and nose-clip previously described an arrangement similar to that used by dentists in the administration of nitrous oxide. This consists of a metal funnel, the stem of which acts as an inlet pipe; it fits with a pneumatic pad against the face, and is fastened on by a strap buckling behind the head.

A safety pipe, fitted with this face piece, is regularly used by men working in the United Alkali Company's sewers, and when cleaning out "Chance" carbonators, vitriol chambers, &c.

The reason we did not adopt this face piece for the rescue apparatus itself was that we felt most strongly the imperative necessity for simplicity and speed of adjustment.

This face piece requires blowing up before use and then buckling on. This was a decided disadvantage, for when the average man is excited and nervous, as he invariably is in cases of emergency, the fewer straps he has to buckle and taps to turn, or stoppers to put in, the better.

I do not think I should conclude this paper without describing the means adopted by the United Alkali Company to ensure that the emergency apparatus which they have placed in each of their works should be in an efficient condition and in its right place.

Each works has to keep a book, in which the results of a monthly examination of all such apparatus is entered. On the front page of this book the following instructions are printed:—

Examination of Emergency Apparatus.

1. Let all apparatus, "safety pipes," "Towers' absorbers," "oxygen cylinders," "ropes and belts," "galvanic batteries," and "eyewash bottles" be examined once a month, and the result recorded in the "emergency apparatus" book.

(A.) The "safety pipe" case contains 50 feet of pipe, a belt with ring, eye protectors, mouthpiece, and nose-clip (attached to mouthpiece), candle, candle stand, and lead acetate papers.

(B.) The "Towers' absorber" consists of absorbing cylinder, leather case, belt with ring, and mouthpiece with nose-clip attached.

(C.) The "oxygen cylinder" should be accompanied by a regulating valve and an inhaler.

2. Test the valves and tubing of the "safety pipes" and "Towers' absorber" in the following way:—

(A.) In the case of the "safety pipe," place a stopper in the inlet end of the pipe; in the case of the "Towers' absorber," pinch the india-rubber tube. Place the mouthpiece in the mouth and suck. If all is tight, the tubing of the "safety pipe" and the outlet valves in both cases are in good order.

(B.) Remove the stopper from the end of the "safety pipe," also do not pinch the tube of the "Towers' absorber;" place a stopper over the outlet valve in both cases. Put the mouthpiece in the mouth and blow. If all is tight, the inlet valves are in good order.

3. Wherever the "Towers' absorbers" have been used, replace the old cylinders with freshly-charged cylinders.

In addition to this, the apparatus in each works is examined once a quarter by a special inspector appointed by the central office in each district.

Of course, the best laid plans have their flaws—flaws which experience alone can discover. The arrangements made and apparatus adopted by the United Alkali Company are new, they have fortunately not yet had occasion to be

used, and all we can say of them is that they indicate an honest attempt to meet the spirit of the special rules laid down by Her Majesty's Inspector of Factories, which is to take the best practicable means of avoiding accidents, and when accidents do occur, of minimising their effects.

NOTES ON POISONING BY CARBONIC OXIDE.

BY DOUGLAS HERMAN.

THE rapidly increasing use of gases containing more or less of the highly poisonous carbonic oxide for heating and illuminating purposes, together with the dense ignorance generally prevailing outside the chemical trades proper, both as to the symptoms exhibited by persons suffering from its effects, and the proper methods of treating them, will, I trust, be sufficient justification for again bringing before you a subject on which I addressed you some nine months ago (this Journal, 1896, 247).

Carbonic oxide is produced in all cases where there is incomplete combustion of carbon, and is present to a greater or lesser extent in producer gas, blast-furnace gases, the so-called "water-gas," either plain or carburetted, in which latter form it is very largely used in America for illuminating purposes, and is rapidly coming into use in Great Britain, in ordinary coal-gas, lime-kiln gases, the spent gases from carbonators in the ammonia-soda process and the after-damp in coal pits, &c.

In the tables given are analyses of these gases.

The introduction of carbonic oxide for heating purposes practically dates from the introduction of the Siemens regenerative furnace. Attempts had been previously made to use it, but the fact that the thermal duty obtained was from 30 to 50 per cent, less than that of the original fuel, and that the pyrometrical effect was also much lower, more than counterbalanced any advantage that could be expected from its employment. The use of the regenerator, however, so modified the working conditions, that where high temperatures are required, producer gas is the more economical fuel. The earlier producers were worked by draught, so that any leakage was that of air into the producer, where it burnt up a portion of the gas, generating heat in the producer where it was not wanted, and leaving less heat to be evolved in the furnace where it was wanted. The forcing of air through the fuel by pressure altered this state of things. A richer gas was obtained at the furnace, and a smaller producer capacity was needed to gasify a given amount of fuel; but the direction of the leakage was reversed, so that the producer gases escaped through any openings into the atmosphere. Bricks and mortar are very pervious to gases. This evil is partially remedied by the pores and crevices being filled with tar and soot, from the distillation and partial destruction of the hydrocarbons; but in the lower part of the producer this filling up of the crevices is much less complete, because there is little or no distillation taking place at that part. In addition to the porosity of the materials there is always less or more heaving of the brickwork, owing to changes of temperature and settling of foundations, which produce fissures and allow the escape of gas. It will sometimes happen that a set of producers which has worked for a long time without accident suddenly becomes dangerous. In such a case it will generally be found to arise from a small fissure, allowing the gas to flow in the direction where the men have to work, or where they may happen to be when at leisure. Hence it is important that the men's resting-places should be at some distance from the producers, and where there is a free circulation of air. There is not much danger from producer gas when the products of distillation of hydrocarbons are present; the men know what they are dealing with, and can take proper steps to avoid danger. The great risk is from the carbonic oxide from the coke alone; the men may continue to breathe it and know nothing about it until it is too late to save themselves. You will notice that in the gases from producers and those from blast furnaces, which are practically big producers, the carbonic oxide varies from 8 to 28 per cent. by volume.

My first experience of carbonic oxide poisoning dates back more than 25 years, when I was called in to ascertain

the cause of the death of two cart horses which had been found dead one morning in the stable of a neighbouring iron works. I noticed that there were many mice dead in all parts of the stable and suspected gaseous poisoning. To ascertain if this suspicion was well founded I had the stable thoroughly cleaned out, to prevent any chance of poisoning by possibly poisoned fodder, and secured in the stable mice, rats, a cat, and a dog. All died except the dog, which had broken loose, and was found in a fainting condition near the door. After being in the stable for a few minutes on this occasion with one of the works staff we both felt a singing in the ears, accompanied in his case with dizziness, and in mine with headache. A cat and dog were also found dead in a store-room adjoining the stables, and men engaged in the store-room had often complained of headache. The only possible source of poisonous gas, in this case, was some producers situated about 50 yards off. On digging a trench across the yard to isolate the producers, it was found that the ground was very open and porous, consisting mainly of cinders. When the trench was filled up with impervious material all complaints of headache, &c. ceased.

The producers in this case were of the open grate type, but they were placed low down and had large cooling siphon tubes, so that there was sufficient pressure to cause the gas to pass for a long distance through ground of the porous nature described.

In the course of this investigation, I noticed that mice were particularly sensitive to the action of carbonic oxide, and I would strongly support the recommendation of Dr. Haldane that they should be employed as a means of giving early indication of the presence of carbonic oxide. In an admirable report, dated this year, to the Secretary of State for the Home Department, "On the causes of death in colliery explosions and underground fires," he says:—"In small animals the rate at which blood becomes saturated with carbon monoxide is far more rapid than in man: hence a small animal, such as a mouse, shows the effects of the gas far more rapidly than a man, although a given percentage of it seems not to be, in the long run, more poisonous to a mouse than to a man. Practically speaking, the condition of a mouse which has been for a very short time in a poisonous percentage of carbon monoxide indicates what will be the condition of a man carrying it after a much more prolonged stay in the same atmosphere. With a man at rest it takes about 20 times as long for the man as for the mouse to be distinctly affected by the gas. Thus, to take an example, I found that with 0.4 per cent. a mouse was distinctly affected in 1½ minutes, and quite helpless in 3 minutes, while I myself was not distinctly affected until after half an hour. The air I was breathing contained about the same percentage as is so often fatal to rescuers. These experiments show distinctly how valuable the indications given by a mouse, or other small animal, would be to men exposed to danger from after-damp. The mouse may be carried in a small cage, or a lamp chimney closed at the ends with wire gauze. When dangerous percentages of carbon monoxide are encountered, the mouse will begin to pant, and show signs of weakness in the legs; should the mouse suddenly become unconscious, danger is imminent. A few white mice might easily be kept in the engine room of the winding engine, or in stables or other places in the pit."

Until very lately, but little was known by toxicologists as to the indications presented in cases of poisoning by carbonic oxide. The only practical indication is in the altered condition of the blood corpuscles, the detection of which depends more upon the observation of the physiologist than anything the chemist can show.

The first indication of poisoning by CO is a dizzy drunken feeling, which very nearly resembles that of intoxication by alcohol.

Another indication is the feeling of cold experienced by the patient in the extremities and indeed the whole surface of the body.

Intoxication by CO and alcohol may perhaps be due to the same cause, i.e. deoxidation of the blood, owing to the presence therein of reducing substances. The principal difference is that alcohol stimulates the action of the heart, the diaphragm and the pectoral muscles, thus increasing the

quantity of air passing through the lungs, so that, within certain limits, its supplies its own antidote. But CO has no stimulating effect, its action is rather to paralyse the whole muscular system. When the limits above referred to are passed, the two forms of intoxication are so similar in appearance that even an expert may mistake one for the other; the only ready means of distinguishing them being the odour of the breath. The absence of any stimulating action by CO makes it all the more necessary for the respiration to be supplemented by other means than that furnished by the organism which is affected by the poison. When the dizzy, intoxicated feeling occurs, the man should be at once taken to the fresh air, for it is likely that worse may follow as soon as the remaining deoxidised blood has had time to reach the nerve centres. Oxygen should be administered with the least possible loss of time. It is of course much more easy to administer it while the man has the use of his own strength and his senses, than after he has become insensible. The similarity of the immediate cause of the two forms of intoxication, suggests the use of oxygen in cases of severe alcoholic poisoning.

In a case of carbonic oxide poisoning reported to me by Mr. James Hargreaves, the cause of the sudden attack was found to be a small fissure in the side of a gas producer, by which a jet of CO issued close to the man's face where he had happened to be sitting down to take a short rest, and so had inhaled a much larger quantity of CO than would occur under ordinary working conditions. This was found by applying lights to the walls of the producer. It is easily conceivable, however, that the CO might be diluted with so much CO₂ and other incombustible gas, that it would not have taken fire, and yet contain enough to do mischief. It will not do to conclude that CO in dangerous quantity is absent because the issuing gas will not produce a flame when a light is applied.

According to Dr. Haldane's report "the key to the peculiarly insidious action of carbon monoxide is afforded by the following two facts. (1.) The affinity of carbon monoxide for hæmoglobin is a very powerful one, so that even when a very small percentage of it is present in the air, absorption by the blood may go on steadily, though slowly, until finally the oxygen carrying power of the hæmoglobin is reduced to a dangerous extent. (2.) The symptoms produced by deficiency in the oxygen supply to the tissues are very slight, up to the point at which there is loss of power over the limbs. When the limbs completely fail, it is of course impossible for a man to get out of the poisonous atmosphere. The affinity of carbon monoxide for hæmoglobin is about 250 times as great as that of oxygen. In other words the hæmoglobin of blood brought into contact with air containing about 0.1 per cent. of carbon monoxide will finally become about equally saturated with carbon monoxide and oxygen. If the same blood be afterwards brought into contact with pure air, constantly renewed, the carbon monoxide is gradually driven out. This process of driving out occurs about five times as fast in pure oxygen. When the blood of the living body has become about 50 per cent. saturated with carbon monoxide there is loss of power over the legs. These facts make it possible to understand the process of gradual poisoning, or of recovery in fresh air. With less than 0.1 per cent. of gas in the air the blood does not become more than 50 per cent. saturated, so that even a prolonged exposure does not cause complete helplessness. With 0.2 per cent. the blood will become about 67 per cent. saturated, and complete helplessness, with loss of consciousness, would doubtless occur. Probably this percentage would finally cause death, from the gradual damage produced by the diminished supply of oxygen to the tissues. 0.30 per cent. would certainly cause death in time. Very little actual distress accompanies the action of carbon monoxide. After paralysis of the limbs the senses are gradually more and more benumbed, as by an anæsthetic. If the percentage of carbon monoxide is large (more than 1 or 2 per cent.) loss of consciousness is followed by convulsions, &c., as in suffocation from rapid deprivation of oxygen. If there is less than 1 per cent. of carbon monoxide death is very gradual and peaceful.

Men who have been for some time unconscious from CO poisoning, or, what is essentially the same thing, want of oxygen, but who have been afterwards rescued, may suffer

for many days or weeks from after symptoms of a most formidable character. A man who has been only partially disabled by CO, or who has only been helpless or unconscious for a short time, will usually recover completely within a few hours. Recovery is accompanied by very severe headache and often by nausea and vomiting. The headache and nausea seem to be more severe the longer the exposure. Dr. Haldane has found, by experiments on himself, that an exposure of several hours to as little as 0.07 per cent. of CO will cause not merely dizziness, &c. on exertion at the time, but a headache afterwards, lasting for about 12 hours."

The second source of carbonic oxide, to which I will refer, is lime burning. Ordinarily the limestone and fuel are thrown in together, and sometimes the fuel is used in somewhat thick masses. In such a case, where the fuel is burnt in the hot air which has been heated by the mass of hot lime below, the high temperature of combustion favours the formation of CO, and if this can get to any point of leakage before a supply of O has reached it, it of course escapes in that condition. If this gas escapes into open gravelly ground, where the upper surface has been rendered dense by being trampled on, &c., there is no knowing at what point it may escape. The composition of the gas that escaped would be very irregular; sometimes CO, at others CO₂, sometimes free O only would pass along with the atmospheric N and as there is no smell to indicate the difference, it could only be judged of by the results, so that a room into which the leakage escaped might be quite healthy for a week together, and then in an hour all its inmates might be killed.

A practical and very instructive illustration of this took place in 1887, at Malaunay, in the neighbourhood of Rouen, where a certain Druaux kept a wine shop, situated in close proximity to a lime-kiln. Druaux and his wife's brother were found dead in the house, and Madame Druaux in a state of supposed intoxication. She was unable or unwilling to give any account of what had happened, or any explanation of the fatalities, and was at once suspected of having administered poison.

Madame Druaux was tried and found guilty. Her avocet was convinced of the innocence of his client, and more by threats than by persuasion he succeeded in having his client set at liberty after an incarceration of five years and nine months.

In October last, the matter was brought before the Court of Assize at Amiens, when the evidence then produced distinctly proved that CO from the lime-kiln was not only the cause of the death of her husband and brother, but also of her supposed intoxication at the time. She was formally declared innocent and awarded 40,000 francs as compensation for false imprisonment.

The limits of these notes will not allow this case to be treated with the fulness which it merits. It is full of suggestions which deserve serious study by manufacturers, chemists, sanitarians, legal practitioners, and medical men.

Mr. T. A. Reid has kindly supplied me with analyses of lime kiln gases, and of the waste gases from the carbonators in the ammonia-soda process. (See table.)

Mr. Reid informs me of a case of carbon monoxide poisoning in which a young man fell into a lime-kiln which had been lit up the previous night, but which was fortunately not in full blast, although the atmosphere was considerably worse than if it had been so, containing quite 9 or 10 per cent. of carbonic oxide. The man was very expeditiously got out, in fact, was in the kiln under five minutes, but the case was such a bad one that four hours was necessary to bring him back to consciousness. Oxygen was administered to him within five minutes of his being got out of the kiln. The effect was quite marvellous, and the renewal of the circulation was quite apparent by the actual change which took place in his face.

The method Mr. Reid uses in applying the oxygen gas to the men simply consists in having the ordinary cylinder fitted with a regulating valve and a length of black india-rubber tubing, into the end of which is put about a couple of inches of clay tobacco pipe stem. This prevents the man compressing the tube with his teeth. The mouth is held and pressure brought to bear on the chest, and while

the pressure is maintained the nostrils are closed as well as the mouth. The oxygen gas acts until it distends the cheeks. The oxygen is allowed to pass out through the nose, the chest being again subjected to pressure. The operation is repeated until the man is conscious.

Mr. James Stelfox, manager of the Belfast Corporation Gasworks, who was one of the first to introduce into this country carburetted water gas on a large scale for illuminating purposes, has been good enough to send me analyses of carburetted water gas and of ordinary coal gas. (See table.)

With respect to these analyses he remarks that 27 to 29 per cent. is the usual proportion of carbonic oxide present in water gas, and 6 or 7 per cent. in coal gas. He mixes the water gas with the coal gas, and has supplied as much as 50 per cent. of the former.

Deaths from inhalation of coal gas are of frequent occurrence—there have been several during the last few weeks. Less than a fortnight ago two women were poisoned at Bath through a chandelier having been drawn down too low.

Dr. Samuel Craddock, of Bath, who attended the victims, writes me that they evidently died from carbonic oxide poisoning, as shown by the crimson hue in the face. One peculiarity he noticed was rigidity from the commencement in the muscles of the arms and legs.

Mr. Stelfox does not consider that there is any evidence to prove that water gas is more deadly than coal gas in practice, both will kill if inhaled in quantity for a sufficient length of time. I have no practical experience with carburetted water gas, but should imagine its action would be similar to that of ordinary producer gas, and that the dangerous constituent in each case, as well as in coal gas, is the carbonic oxide. If this is so, and I think there can be very little doubt upon the point, it is evident that a gas containing a large proportion of CO must, when it escapes into a room, be more likely to prove fatal to the occupants than one containing a much smaller proportion. In this connection the following table by Dr. Haldane, who has devoted very special attention to this subject, and which I have abstracted from his report already referred to, will be of interest. (See table.)

Having regard to the manifest advantages under certain conditions, of carburetted water gas, I should not be disposed to oppose its use under proper regulations, but I hope before its use becomes general here similar precautions will be taken as, according to Dr. Wynter Blyth, are observed in America, to guard against the danger from escapes owing to the careless manner in which gasfitters usually perform their work. In America, before the gasfitter asks the company to make the connection with their main he proves the pipes. All the outlets which have been left for brackets and pendants, &c. are, with one exception, stopped up either with plugs or screwed caps. A force-pump containing a few drops of sulphuric ether is then attached to the outlet which has been left, and the pump is set to work until a high pressure has been registered. A high pressure is necessary, for the iron pipes may have many latent weaknesses—pinholes filled with grease, seams just ready to burst, &c.; these, when a high pressure is employed at once become apparent. When the gauge indicates a certain figure the pumping ceases, and if the mercury falls it is evident that there is one or more palpable leaks, which are at once sought for and remedied; the sulphuric ether will aid in their detection. Before the connection with the main is made, an inspector in the employ of the gas company carefully and closely scrutinises all the pipes, bends, joints, plugs, &c. where brackets and chandeliers are intended to be fixed, and should he in any of these discover the slightest weakness or departure from the rules, he insists upon all being made right. The pump is set in action before him, and if the pipes are now airtight, he has simply to cast an eye upon the gauge, the column of which will no longer sink; and if all is satisfactory he signs the requisite order.

I do not purpose saying anything to-night about the last two gases on the table, "after-damp," and the gases left along the track of an explosion in coal pits. They are fully dealt with in Dr. Haldane's valuable report.

I commenced my notes by lamenting the ignorance prevailing with regard to the treatment of sufferers from carbonic oxide poisoning, and I cannot perhaps conclude more appropriately than by calling your attention to some very useful work on the part of the "Chemical Trade Journal." Impressed by the fact of the gross ignorance generally existing with respect to gaseous dangers, and by the alarming frequency with which accidents of this kind have been converted into fatalities, to the consequent great discredit of the chemical trade, this paper set before itself the task of popularizing and promulgating a knowledge of the dangers and of the most effective means for their prevention and remedy. This information is codified and condensed in an article which appeared on the 24th of October last, and the whole matter is summed up in a series of rules which the proprietors issue in the form of a poster. You will, I am sure, be interested in hearing that already the manufacturing world, both here and on the other side of the Atlantic, has shown a keen appreciation of this effort to meet a cogent though, perhaps, somewhat ill-defined want.

DISCUSSION.

MR. FORBES CARPENTER said he had listened with deep interest to the two papers which had been read. It would be known to them that Mr. A. E. Fletcher (late Her Majesty's Chief Inspector of Alkali, &c. Works), who was a member of the Committee, was consulted in the drawing up of the rules issued by the Home Office, and therefore, although not officially, they came under the cognisance of his Department. He would like to ask Mr. Carey if among the subjects which came under his notice, during the course of the investigations, any absorbents had been found which were capable of successfully dealing with the oxides of nitrogen. He was interested to see that Mr. Davis, who was responsible for the article in the "Chemical Trade Journal" of October 24, had placed the oxides of nitrogen

amongst the most dangerous gases, more dangerous even than sulphuretted hydrogen. In his (Mr. Carpenter's) address to the Manchester Section in 1894 he commented on a book that had then recently appeared on the "Diseases of Occupations," by Dr. J. T. Arlidge, and he noted there that he did not think the author had fully grasped how serious were the effects of exposure to oxides of nitrogen. It was a fact that the effects were not felt at the time, but only after a lapse of some hours, and when the man, who had been exposed to these gases, was compelled to call in medical assistance, the case had often been found to be very serious, pneumonia setting in, followed in many cases by death. It was important that this subject should be ventilated and discussed, because he did not think the factory inspectors were perhaps aware that this was one of

the cases which science had not, so far as he knew, been able to deal with in the way of absorption. It had led to a little friction between the Factory Acts Department and manufacturers, inquiries having been made as to why respirators were not used in certain cases.

With regard to Mr. Herman's paper he might say he was at Bath quite recently and had some conversation with the manager of the Gas Company's Works, where they had recently installed a water-gas plant; he put to the manager the argument that Mr. Herman had used as to the increased percentage of carbonic oxide being a source of danger to consumers, especially of the poorer classes. Mr. Ellery's reply was that the odour of the mixture of coal-gas and carburetted water-gas was sufficient to draw attention to the existence of a leak, so that it was more a theoretical than a practical objection which would be raised. Further, he had stated that in America there were not more deaths due to water-gas than in England, where the percentage of carbonic oxide in coal-gas was stated to be from 6 to 7 per cent. Mr. Carpenter thought, however, that statistics had been quoted to show that deaths had been more frequent since the introduction of water-gas and he was rather startled to hear of the two deaths at Bath on the day following the visit to which he referred.

Mr. GEORGE E. DAVIS remarked that he was pleased to find that Mr. Carey had gone into such minute details, as the process of introducing oxygen from a high-pressure bottle into a workman's lungs was not an operation to be thought too lightly of. As to the choice of the best respirator, experience had taught him that respiration should take place through both nostrils and mouth, and he did not think very highly of any apparatus which closed the nostrils. With reference to poisoning by carbonic oxide, members should bear in mind that water-gas was now being largely distributed by certain gas companies and in his opinion deaths by gas poisoning would now be more frequent. During the water-gas boom of several years ago the gas companies endeavoured to show how dangerous was the attempt to distribute water-gas; he would certainly say that a gas containing so large a proportion of carbonic oxide should not be used as an ordinary gas supply, except under proper regulations. The leakage from ordinary gas-taps was not a small figure, and if gas-works, from motives of economy, persisted in distributing a very poisonous mixture, which certainly was not intended in any of the Acts of Parliament under which their works were established, they should do so under special rules and regulations.

Mr. H. PORTER said he had been for some years connected with the manufacture of gun-cotton, and the decomposition of the gun-cotton in certain states of the atmosphere was a weekly or daily occurrence; the decomposition went on rapidly with evolution of dense brown fumes, and this necessitated the attendance of men to overturn the pots in which the gun-cotton was put to cool. He himself had been in such an atmosphere, and breathed without difficulty, for half an hour at a stretch, the only precaution he took being to fill his mouth with water and so compel himself to breathe merely through the nose. He would like to know if Mr. Carey had had experience in this direction.

Mr. T. A. REID observed that the question of treating people overcome by noxious gases was a public question, for there were many instances, outside the chemical trade, where noxious gases were produced, as, for instance, in the case of blast-furnaces, lime-kilns, water-gas plant and ordinary coal-gas. He had had experience with most of the types of apparatus exhibited, but he must say he had objection to the apparatus depending on the use of an absorbing medium for purifying the air before admission to the lungs. His experience was that in use it had a very tiring effect on the lungs, and for some purposes, of course, it was not applicable at all, as, for instance, in the case of lime-kiln and blast-furnace gases, waste gases from the ammonia-soda process, coal-gas, and producer gases. He was strongly in favour of the apparatus shown with air-pipe attached; this type was in daily use at the works of Messrs. Bowman, Thompson, and Co., Ltd., at Lostock Gralam, as a preventative, when cleaning out tanks, which were liable to contain such gases as had been mentioned.

Men equipped with this were able to work for 20 minutes at a spell, without any discomfort, in an atmosphere which would prove fatal in a few minutes to men not so equipped. He was of opinion, however, that it would be better to have the apparatus on a reel, so that, when not in use, the air could blow well through it. With regard to the use of oxygen, he considered the oxygen bottle to be an essential part of a works equipment if there was any liability at all of dangerous gases being met with. As Mr. Herman had mentioned, he had had numbers of cases of asphyxiation by noxious gases, but no fatal cases had occurred since the oxygen bottle had come into use.

Mr. A. SMITHAM described how he and two assistants were poisoned by working in an atmosphere containing only comparatively small proportions of carbonic oxide; one of his assistants was ill for a week, but the other and himself, beyond the intoxicating effects described by Mr. Herman, noticed no serious after-effects.

The CHAIRMAN conveyed the hearty thanks of the section to Mr. A. Carey and to Mr. Herman for their interesting and suggestive papers. The subject of Mr. Carey's paper was of the greatest practical importance and the line of work as carried out—that of prevention rather than of cure—was based on an exact knowledge of the conditions under which the poisonous gases referred to were met with. In regard to carbon monoxide poisoning he had had occasion recently to inquire into the extent to which it occurred in the United States in the use of plain or carburetted water-gas, and had been informed, on reliable authority, that the fatalities were not excessive. In comparing the poisonous effects of carburetted water-gas and ordinary coal-gas, it was desirable to bear in mind that the latter also was a powerful poison, and that in the case of an undetected escape, fatal results might follow from either. The absence of smell in ordinary water-gas could, of course, be overcome. He was very glad to see how fully Mr. Herman had appreciated Dr. Haldane's masterly work on carbon monoxide poisoning.

Mr. A. CAREY, in acknowledging the vote of thanks, referred to the several points raised in the discussion. In reply to Mr. Carpenter's question as to whether they had come across any satisfactory absorbent for the oxides of nitrogen, he said they had not; so that whenever they had reason to suspect the presence of the oxides of nitrogen they found it necessary to use the "safety pipe." He considered that the fact that some men were able to work at the cleaning of vitriol chambers or Guy Lussac towers without injury while others were seriously affected was largely due, not to any particular knowledge of how to breathe, but to the different powers possessed by the men of resisting the action of the gases. Mr. Herman had likened poisoning by carbon monoxide to alcoholic poisoning. There was not much doubt as to the varying power of men to resist alcohol, and he thought that the same idea was applicable to other gases than carbon monoxide. Mr. Porter had spoken of the oxides of nitrogen, and said that by filling the mouth with water and breathing through the nose it was possible to resist their effects, but he (Mr. Carey) failed to understand this; the damage done by the oxides of nitrogen was in the lungs, and the gases would get there through the nose as surely as through the mouth. Mr. Davis had said he disliked the respirators because they did not permit breathing through the nose, and that if a man had not his nose to warn him he might continue to use a respirator when the purifying material was exhausted. He thought Mr. Davis did not quite realise the object for which these respirators had been recommended, which was for rescue purposes, when a few minutes' exposure to the noxious atmosphere would be all that was required. The respirator, moreover, which he had already described, containing an absorption chamber of 50 cb. in. capacity, would last in an atmosphere containing 5 per cent. of H_2S by volume, about 80 minutes.

Mr. HERMAN questioned whether the odour imparted to water-gas would arouse a person from a sound sleep. It was during sleep in a closed room that danger from an escape of CO was most to be feared. Possibly the reason that there were not more deaths in America arose from the fact that the fittings were better looked after.

NOTE ON A SUBSTITUTE FOR TARTARIC ACID IN GASOGENES.

BY DOUGLAS HERMAN, F.I.C.

Abstract.

FOR one purpose for which it was commonly used, however, and that perhaps not the least important as regards quantity consumed, tartaric acid was by no means essential. He alluded to the preparation of carbonic acid, particularly in the domestic gasogene or seltzogene. Of course, in the manufacture on a large scale of aerated waters, sulphuric acid was used, but its employment in the ordinary gasogene was evidently out of the question. But although the difficulties attending its use for this purpose appeared insuperable when the acid existed as a liquid, they vanished entirely when the acid was supplied as a bisulphate in the solid form which he had the pleasure of bringing to the notice of the members that evening. The idea of employing a bisulphate for the liberation of carbonic acid from carbonates was not new, and he believed it had been applied in factories; but there were several practical difficulties in its application to gasogenes which had only recently been surmounted. In the particular form which he exhibited, however, the difficulties were not only overcome, but some advantages were obtained. Thus the bisulphate being cast in moulds of definite size, in order to pass easily into the gasogene, and the moulded blocks forming a package of regular size and shape, it was at once patent to the eye of the user that the correct charge was present, and the safety of the gasogene was assured. The solid blocks of bisulphate presented much less surface to the solvent action of the water than did small crystals of tartaric acid; hence the evolution of carbonic acid was more gradual and uniform, ensuring better aeration of the water without undue pressure.

Although the evolution of carbonic acid from the bisulphate charges was more gradual than from tartaric acid charges, yet, owing to the fact that in the former case it was practically uniform during the whole period, the aeration was complete quite as soon. The proportions of bisulphate and bicarbonate were so adjusted that the solution in the top globe was always faintly alkaline.

The advantages incidental to the form of packing were briefly reviewed, attention being called to the absolutely moisture-proof nature of the wrapping employed for the bisulphate. Mr. Herman also pointed out that sulphuric acid was still one of our staple manufactures, and it was to our advantage to substitute it wherever possible for a more expensive article, the greater part of the cost of which must of necessity be sent abroad.

CONTRIBUTIONS TO THE ANALYSIS OF FATS.

BY DR. J. LEWKOWITSCH.

VII. *The Gravimetric Determination of the Bromine Value.*

THE determination of the Hübl iodine number is one of the most useful tests in the analysis of fats, and if carried out in accordance with the directions of the author of this classic method leads to unmistakable results.

It is true that the theory of this process is not yet fully understood, and it is no doubt due to this that almost every chemist who uses this method introduces some insignificant modification, and, what is worse, rushes into print forthwith.

Latterly several experimenters have directed their attention to the bromine absorption value, which had been almost wholly superseded—and rightly so—by the Hübl method. The most notable of the papers dealing with this subject is that published by Hehner (*Analyst*, 1895, 50), and although he expressly states that he does not intend to propose a new method, but merely submits a study, we find in a later paper by the same author (Hehner, *ibid.*, 1896, 118) the positive statement that the action of bromine on unsaturated fatty substances is complete and quantitative.

This latter statement seemed hardly reconcilable with the well-established fact that hydrobromic acid is evolved when bromine acts on unsaturated fatty substances—a fact on which Hehner dwells at some length. For this reason it seemed to me desirable to examine Hehner's method more closely.

Some of the results obtained by closely following Hehner's directions are given in the subjoined table:—

Substance.	I. Bromine Value found by the Gravimetric Method.	II. Iodine Value calculated from I.	III. Hübl Iodine Value Experiment.	IV. Mean Hübl Iodine Value.
Olive oil	51.69	81.09	83.77	82
	50.80	80.62
Rape oil	62.63	96.40	..	100
Castor oil	39.09	62.04	..	84
Cotton-seed oil	48.51	79.39	..	108
Linseed oil	18.68	29.65	..	175
	16.4	16.5
Fish oil	18.92	30.02	..	127—150
	16.7	16.98
Oleic acid ("saponified")	36.10	57.30	80	..
	33.83	53.70	80	..
	12.43	67.34	80	..
	41.00	65.22	89	..
	41.43	65.75	89	..
	13.05	68.29	80	..
	14.51	70.63	80	..
	42.75	67.84	80	..
Mixed fatty acids from a household soap.	13.84	21.97	47.92	..
	13.45	21.35	47.92	..
Mixed fatty acid from a household soap.	25.50	40.46	54.86	..
	23.58	37.43	54.98	..

It is certainly very remarkable that in the case of olive oil and rape oil so close an agreement between the gravimetric bromine number and the Hübl iodine value is obtained. In all other cases the discrepancy is very great; in some cases even enormous. The drying of the brominated fatty substance at 125° C. until constant weight is obtained took in the case of, e.g., linseed oil and fish oil, a remarkably long time, considerable decreases in the weight being noticed after each drying.

The introduction of the gravimetric bromine process into fat analysis as a quantitative process must therefore be out of question.

MR. F. S. NEWALL IN THE CHAIR.

CHAIRMAN'S ADDRESS.

BEFORE beginning to read my address I should like to thank you most warmly for the honour you have conferred on me in electing me your chairman for the current session. I am deeply conscious of the responsibility of the position, following as I do in the footsteps of your past chairmen, who have been most intimately connected with the syndicate which practically controls the chemical trade of this district, and have had, therefore, a far wider field for the accumulation of that knowledge of general chemical matters which is so necessary for the Chairman of this Section.

One is met also by another great difficulty, namely, that, from a business point of view, chemical transactions cannot in many instances be made public. It is a selfish trade, for when a man has invented a good process, he does not wish to disclose it or to give the world the benefit of it.

These then I suppose are some of the reasons why Newcastle does not supply this Section of the Society of Chemical Industry with more papers upon chemical subjects. There is no doubt that pioneers of chemistry have certainly had their birth on Tyneside, and, in the present day, we have only to look round to see that talent is not wanting, but both talent and individual enterprise are warped and thwarted by amalgamations and unwieldy syndicates.

This want of activity is no new complaint and if you will allow me, I will quote from the Chairman's address of ten years ago:—

"It was a matter which had already been mentioned in the Committee's report and which is of such importance that he could but refer to it once more. He need scarcely say that he referred to the most striking feature in that report, viz., the great falling-off of the number of communications. The majority have been in the form of short notes merely, and one-third of the communications come from a foreign source. He would not emphasize this latter fact, for science recognised no nationality, but this, together with the small number of communications would appear to denote a want of activity, if not of interest, in the objects for which this Society was formed."

You see, therefore, that the difficulty which was then felt still exists and it is a lamentable conclusion that the impossibility of unfolding new processes and chemical inventions to the world, is one which cannot be easily overcome, and which of necessity very much limits our powers of conference.

There is, I think great scope for investigation in some processes of the past generation, and which though now disused and out of fashion, might be brought to life again by means of modern appliances.

It is upon such a subject that I propose to speak to you to-night, and I am very glad to have this opportunity of bringing it to your notice.

It is most difficult after the lapse of years to collect the details of an extinct process; books get lost, men who have worked at it get separated, or also become extinct, and the details of management are forgotten; and it is only my extreme desire that some account of the oxychloride of lead process of making white lead should be placed on record that has encouraged me to collect and set the following brief sketch before you to-night.

This process was invented by my grandfather, Mr. Hugh Lee Pattinson, and worked at the Washington Chemical Works from 1850 to 1871. Mr. Pattinson was born at Alston on Christmas Day 1796, where the lead industry was then of no mean importance, and it always seems to have had a fascination for him.

In 1833 he patented his process for desilverising lead, which has since been identified with his name, and upon which he read a paper before the British Association at their Newcastle meeting in 1838. After this process was perfected he turned his attention to the manufacture of white lead, and in 1848 invented the oxychloride of lead process. He was, at that time, carrying on the chemical works at Felling with Mr. John Lee, and had with him as assistant Mr. John Glover, who was extremely anxious to get a greater insight into the science of chemistry than he could do by merely working in the works, and persuaded Mr. Pattinson to allow him to work in the laboratory. Mr. Pattinson all this time was looking round for a suitable spot on which to build his white lead works, the great desideratum being an ample supply of good water. This he found at Washington coming straight from the limestone, and in 1846 he asked Mr. Glover to leave Felling and go to Washington to complete the white lead process.

Mr. Glover was then experimenting on his plan of denitrating sulphuric acid by means of the pyrites kiln gases, but he gave up the experiments, which were not continued until he completed them at Washington in 1857 by inventing the tower which bore his name and is universally adopted in chemical works of the present day.

You will see from this that the collection of the particulars of this process has been confined to very few individuals, and those who now remember its details are scattered far and wide, and it has been impossible to confer with them all.

Galena, in charges of about 6 tons, in the state in which it arrived from the lead mines, together with the necessary quantity of hydrochloric acid of 30° Tw., was put into a mill constructed of a wooden tub, 20 ft. diameter by 5 ft. deep, lined with lead and blocks of grey granite 9 in. square, which were set in asphalt. An agitator of strong oak beams, secured with copper bolts, carried round large blocks of granite, with which the galena and HCl were ground together, the result of the reaction being to produce lead chloride and H₂S, which was evolved in large quantities. Of this H₂S I will speak later on.

The free acid contained in the HCl used in these dissolvers was not by any means neutralised by the galena, but a considerable quantity remained, so that when, on testing, the acid was found to be about 10° Tw., the whole contents of the dissolver was run into a settling tank. Here the density of the PbCl₂ made it settle rapidly and the clear supernatant liquor was syphoned off. The PbCl₂ was washed with successive quantities of cold water to remove the last traces of free acid and salts of iron, which if not eliminated at this stage caused the resulting white lead to have a yellow tint.

It is hardly necessary to state the reason for using cold water instead of hot, which is of course on account of the slight solubility of PbCl₂ in cold, while it is freely soluble in hot water—it requires 135 lb. of water at 12° C. to dissolve 1 lb. of lead chloride and only 20 lb. of water at boiling point.

The removal of iron at this stage was one of the great difficulties of the process, finally overcome by using a peroxide, which caused the precipitation of ferric oxide in a manner well known and very commonly used. The results of many experiments showed that by dissolving lead chloride in boiling water, and adding at the same time small quantities of peroxide of lead, the liquid, after settlement, was perfectly free from iron and gave a pure white resulting product.

By the adoption of this process the number of washings with cold water could be reduced from 12 to 3 or 4, and thus a saving was made, as every washing carried away with it in solution an appreciable quantity of lead chloride. This plan was Mr. Glover's proposal, and in all probability he was the first, or among the first, to use peroxides for the removal of iron.

The chloride of lead was therefore washed from the settling tank with boiling water (and a quantity of from 4 to 5 lb. of peroxide of lead per ton of $PbCl_2$ added to remove the iron) into round vats, lined with lead, and fitted with agitators, the agitation being kept up until all the chloride was dissolved, when it was run into stock vats, 20 ft. diameter by 12 ft. deep, and allowed to settle. The heating to boiling point of the immense quantity of water required was a matter of considerable moment, and large haystack boilers were used, the water being passed from one to the other. We have now got the clear chloride of lead solution free from iron and all other impurities, and to precipitate it requires a large volume of lime water. The quantity of lime required to precipitate the lead having to be in the form of clear lime water will show you at once what immense quantities must be used for the purpose, as the solubility of lime in cold water is about 1 in 750. This lime water was prepared under cover in large brick tanks, about 100 ft. square and 8 ft. deep, and there were three of these.

One of the difficulties Mr. Pattinson had to contend with was getting an intimate mixture of these two solutions in the right proportions, for an excess of lime water made the lead yellow; and in order to maintain a constant head of liquor on the mixing pipes two stone tanks, about 4 ft. square by 12 ft. high, were used. These had gauge glasses fitted the entire height, and the man in charge had to keep an equal level in both tanks, into which chloride of lead and lime water were respectively run from the stock tanks. From the bottom of these tanks taps allowed the liquors to run to the mixing pipes, 6 in. diameter by 12 ft. long, along which a narrow slit ran the entire length. From these slits the liquors emerged in thin films, and were thus intimately mixed; passing on, it entered at the periphery of a circular tank with a central opening, forming a vortex action and completing the mixture. Hence they flowed into draining tanks, which settled and filtered the precipitate. As the clear filtrate passed away it was treated with a small quantity of bicarbonate of magnesia solution in order to precipitate any chloride of lead which might still remain in solution. It was found in practice that the oxychloride of lead, after being ground with oil to form paint, used to set hard in the casks, and to obviate this difficulty Mr. Pattinson added in the mixing tank a quantity of bicarbonate of magnesia, forming a basic carbonate of lead along with the oxychloride of lead having the formula $PbCl(OH)$.

The result was filtered from the tank, filled into earthenware dishes, and dried in the usual manner. It was of good colour—many considering it superior to Locke Blackett's white-lead, which I believe then stood highest in the market; and as for covering capacity, Mr. Pattinson used to claim for it that 60 lb. of oxychloride would go as far as 100 lb. of other paints. The quantity of white-lead made by this process averaged about 1,000 tons a year during the time the process was at work at Washington.

Such is a brief outline of the process, but I must ask you to let me take you back, to learn what happened to the by-products. The first of these was sulphuretted hydrogen, evolved on the decomposition of galena with HCl . This gas coming off in irregular quantities, was first taken in pipes to the pyrites kilns, and the products passed into the sulphuric acid chambers, but caused endless trouble, besides the danger occasioned by flashing back through the supply-pipes, producing explosions. To obviate this, a small gas-holder was made of gutta-percha. This was a most costly affair, and only lasted a very short time, for one day it suddenly exploded, and the fragments were too small to enable anyone to assign a cause for its dissolution. After this the gas was burnt under a boiler fire, and the products passed up the chimney. The undecomposed galena left in the settling-tank after the chloride of lead had been washed from it, contained all the silver originally in the ore, and many were the experiments made in smelting-

furnaces to recover this. Mr. Pattinson always wished to recover the silver in solution, and if he had done this, would have considered his process a complete success. He, however, was not spared long enough to complete his experiments, for he died in 1858. Mr. Glover, who had so ably assisted him, left Washington in 1861, and the question of extracting the silver and lead from the residuum remained unsolved.

In spite, however, of these advantages, the process was discontinued in 1874, and the works dismantled. A rapid fall in the price of white-lead, and the low prices realised for the residuum, which, as years went on, did not decrease in quantity, made it impossible to carry on the process at a profit.

The sources of loss in a process involving such large quantities of liquid are large, and although every possible care was taken, lead *did* get away undissolved, unprecipitated, and unfiltered.

If HCl could be spared in quantities, I have no doubt that this beautiful process could be economically worked with the modern disintegrators for grinding the lead ore before putting it among the acid, the perfected process for recovering sulphur from H_2S , and the excellent appliances we now possess for mixing and filtering solutions.

Mr. JOHN PATTINSON moved that a hearty vote of thanks be given to Mr. Newall for an address of exceeding interest.

Dr. BEDSON, in seconding the motion, congratulated the Section on having secured Mr. Newall as its chairman, and congratulated the chairman upon an address which was a distinct addition to chemical literature.

Mr. JOHN GLOVER, at the request of the chairman, spoke of the share which he had had in the working of the oxychloride of lead process, and also addressed a few words of advice to the younger members of the Section, urging them to add to their purely chemical knowledge a knowledge of mechanics and of constructive materials, pointing out that some such knowledge was essential to a man who had to carry out chemical reactions on a large scale.

He also spoke of the very great pleasure that it had been to him to receive the first medal of the Society, and that he regarded it not merely as a personal honour, but also as an honour bestowed upon the Newcastle Section of the Society.

MR. F. J. R. CARULLA IN THE CHAIR.

CHAIRMAN'S ADDRESS.

The Commercial Position of Sulphate of Ammonia.

It is chiefly the farmer who has been kept in view when making comparisons between the price of sulphate of ammonia and that of its great rival, nitrate of soda. The last contains 16.47 per cent. of nitrogen, whilst in sulphate of

ammonia this reaches 21·21 per cent. It is obvious that, reckoning the unit of nitrogen as of equal value in both, the price of sulphate should exceed that of nitrate by more than a fourth, and this condition held good until not very long ago when a reversal occurred, the causes of which are not at all easy to fathom. It may safely be said that, had the synthetical manufacture of ammonia from the nitrogen of the air been accomplished on a commercial scale, the revolution experienced could hardly have been greater.

How industries can be influenced by methods other than those of a purely technical nature is well illustrated by the following extracts from a letter signed "Nitrogen," which appeared in the *Chemical Trade Journal* of the 15th of last August:—

"Some 16 or 18 years ago, when sulphate of ammonia sold at a very high price in relation to nitrate of soda, and when sulphate of ammonia alone was used as a manure for sugar beet, the nitrate of soda producers bethought themselves of a scheme whereby they could displace sulphate of ammonia, and induce the cultivators of beet to use nitrate of soda instead. They offered a prize of 1,000*l.* to the writer of the best essay upon the application of nitrate of soda for beet-growing in substitution of sulphate of ammonia. From that day to this, step by step, nitrate of soda has encroached upon the old preserves of sulphate of ammonia, until to-day we stand in the extraordinary position of being completely routed from a field that formerly was all our own. . . . The price of nitrate of soda to-day is, say, 8*l.* per ton. The price of sulphate of ammonia is to-day, say, 7*l.* 12*s.* 6*d.* per ton. . . . Now what does all this mean? . . . Assuming the export of nitrate of soda is one million tons per annum, then it means that the nitrate of soda producers are now receiving 2,087,500*l.* per annum more than they should receive. A fair return for 1,000*l.* prize once given! ! !"

It cannot be questioned that the literature that arose round this prize must have benefitted the nitrate of soda industry, but the effect in any case has been gradual, and we must remember that comparatively low prices were experienced in the sulphate market long before the prize-essay. In 1867, for example (I take the figures of Messrs. Bradbury and Hirsch), the average price of sulphate of ammonia was 11*l.* 10*s.*, from which figure it rose to 21*l.* in 1872, coming down to 17*l.* 2*s.* 6*d.* in 1874, rising again until 1878, when 20*l.* 5*s.* per ton was realised as an average for the year. This was about the time of the nitrate essay. It will thus be seen that severe fluctuations and low prices were not unknown before its advent. Hence the value of the suggestion that sulphate of ammonia makers should band together and offer a similar prize to sing the praises of their product is questionable. The money would be better spent in disseminating the literature we already possess amongst the farmers to teach them the value of nitrogenous manures generally, rather than make any attempt to fall foul of nitrate of soda. The Sulphate of Ammonia Manufacturers' Association, of which my worthy colleague of Manchester, Mr. Geo. E. Davis, is Hon. Sec., publishes an excellent pamphlet on the use of sulphate, that only wants distributing with a little energy to cause surprise to those apathetic manufacturers, who look with indifference on the association, forgetful of the motto: "United we stand, divided we fall."

It would appear from estimates made by M. Legrand, given in M. Truchot's recent book "L'Ammoniaque," that Belgium uses but $\frac{1}{10}$ th, Germany $\frac{1}{20}$ th, France $\frac{1}{10}$ th, and England $\frac{1}{10}$ th of the quantity of nitrogenous manures they might each consume with advantage. It may thus be seen how great is the field that lies unconquered at our very doors, and the instruction of the farmer is only needed in order to have a flourishing market for our sulphate with benefit to the whole community. The matter is so notorious that numerous references to it are to be found in the reports of Mr. A. E. Fletcher, late H.M. Chief Inspector under the Alkali & E. Works Regulation Acts.

Thus in the proceedings during the year 1889 (p. 12) he wrote: "Seeing that the larger proportion of this ammonia is produced in the gasworks scattered through the country, it appears surprising that the British farmer does not see it to be to his interest to buy that which may be had in his

own market town rather than to allow it to be carried away and shipped for the use of the farmer in Germany, who has to pay the carriage and other charges in addition to the price for which our farmers at home could purchase it."

With our present means of manufacture over-production should be impossible in the face of such figures as those given above, and yet the accumulation of stocks in the hands of the large makers, which, for instance, at the beginning of 1895 amounted to something like 16,000 tons according to Messrs. Bradbury and Hirsch, is a fact that would lead one to suppose production was in excess of demand. Sulphate of ammonia and nitrate of soda are evidently fighting for a restricted field that by combined efforts might be greatly enlarged to the benefit of both.

The accompanying table gives the production of sulphate of ammonia in the United Kingdom during the last 10 years, and the diagram represents the annual variations in the quantities obtained from the various sources. Each division represents 1,000 tons.

AMOUNT OF SULPHATE OF AMMONIA PRODUCED IN THE UNITED KINGDOM DURING THE LAST TEN YEARS.

Shale-works	26,500	23,705	28,485	32,801	38,335
Ironworks	6,290	11,000	8,833	10,075	14,588
Coke, &c. works	2,766	4,973	3,265	3,418	7,983
Total	143,506	149,826	152,762	160,048	179,651

A mere glance at the diagram will show how last year every branch of the industry contributed to the increased production, which rose from an average of barely 6,700 tons for each of the previous eight years, to the astonishing figure of 19,603 tons, an addition to the market supplies that largely explains the depression, already in an acute stage at the end of 1895, when sulphate touched 8*l.* 10*s.*, the lowest price then on record.

It may be that errors in the manipulation of stocks at the large gasworks have aggravated the situation. It is obvious, however, from the diagram that the annual increase in production from such works is only that naturally due to the spread of the gas industry. This increase has not been so great of recent years as it was in 1888 and 1889, years that show remarkable advance. Can the falling-off be due to the progress of the electric light? We cannot doubt that this must in some degree have affected the output of gas, and hence of sulphate.

The use of oil-gas and of the water-gases, in which latter category acetylene may be included, will also tend to prevent any large increase in the output of coal-gas. The Birmingham Corporation have, for instance, established works for the manufacture of water-gas to be enriched with "Russian solar distillate," a petroleum whose specific gravity is nearly 0·80, which will yield 2,000,000 cb. ft. of gas per day of 24 hours, or about a quarter or a fifth of the average output of the Windsor Street Works, while the further extension, for which room is provided, will bring up the capacity to a third of the present output.

That extensions of this character will exert a powerful check on the production of sulphate from gasworks is clear. Acetylene promises also to be soon a familiar feature in view of the establishment of a company at the Falls of Foyers for the manufacture of carbide of calcium.

That the increasing use of coal-gas for cooking and heating purposes will influence the position in the opposite direction is equally certain, and not only for the sake of the gas industry but in the interests of the public health we must all sincerely hope that this will prevail.

Turning now to the ironworks, which help to swell the output of sulphate, I cannot do better than read to you again from one of Mr. Fletcher's reports to give you some idea of what is being accomplished. "There are cases where more of the capital invested in an iron smelting work is devoted to the collection and treatment of the tar and ammonia than to the production of the iron itself. . . . In Scotland at present the apparatus for collecting the ammonia, tar, &c. from the gases of the iron blast furnaces has cost over 444,600*l*." (Alkali Act Report for 1891.)

You will have observed that practically the whole of the sulphate of ammonia from ironworks is obtained in Scotland, and we may suppose that this make is largely added to that portion of the product from the shale works that finds an outlet at Leith. Can it be that this plethora enables speculators to so easily squeeze prices at that port? The iron manufacturers, however, or at least some of them, care as little for low prices, as do those engaged in the English gas industry, and it has been suggested that the ammonia from the blast furnaces should be recovered as carbonate instead of sulphate. This would certainly save the cost of the sulphuric acid and utilise the carbonic anhydride which now goes to waste. As R. Warrington has, however, shown the prejudicial action that ammonium carbonate has on nitrification it may yet be questioned whether the adoption of the suggestion would relieve the situation for the ironmasters.

Modern developments may, however, make such progress as to render the farmer altogether independent either of sulphate or of nitrate. You will be able to read in the forthcoming number of our Journal a report of Dr. Voelcker's paper on "Nitragin," the name given to a bacteriological culture which is to do away with nitrogenous manures at least for leguminous plants.

Although as yet the inroad of the bacteriologist into the domain of the agricultural chemist extends only to the requirements of these plants, it is well to ask ourselves what, if by further developments, nitrogenous manures can be dispensed with altogether? Clearly the nitrate of soda industry would suffer more than sulphate of ammonia, not only because it is the favourite, but also because the trade in nitrate is the larger. Were we in the position of some 28 years ago when the Heaton (Steel) process was invented, and which promised to consume enormous quantities of nitrate of soda, hopes might be entertained that with lower prices its use might increase even if it became obsolete for agricultural purposes. No such hopes are now possible, for with the modern steel processes to compete against that of Heaton could only find employment for exceptional purposes however much it might be technically perfected. It is difficult to imagine in what direction the large quantities of nitrate of soda used in agriculture could be otherwise employed.

The ammonia interest, although also a sufferer, would not be in quite so bad a plight. In the first place the quantity to be reckoned with is much smaller, and secondly, the outlets for ammonia in one form or another are daily widening. Of course I am referring here to ammonia not in the form of sulphate. Already considerable quantities of ammoniacal liquor go into consumption in the ammonia-soda process, amounts that are not included in any of the figures above given. The quantity of ammonia to thus find employment will probably go on increasing until double the present amount is used. The ammonia-soda process last year overtook the Leblanc process as regards the quantity of salt decomposed in Great Britain.

The use of ammonia for refrigerating purposes is also extending.

America has occasionally absorbed a considerable quantity of sulphate from England to be reconverted into ammonia. This may have occurred exceptionally, but it can hardly be a visionary thing to hope that the development of South Africa under British rule may make demands upon us in this direction.

It is needless to dwell on the many purposes for which ammonia may find employment in the house. As the public become more alive to its value as a detergent the use for this purpose must largely grow in importance.

I refrain from mentioning other outlets for ammonia that will be obvious to you for the manufacture of compounds used in small quantities, and over the consumption of which we can exert no influence. Nitrate of ammonia, the offspring of the two great rivals we have been considering, and which has been used in the manufacture of explosives, may be given a passing notice. At one time there was promise of both sulphate and nitrate being largely used in the manufacture of this salt, but its hygroscopic character has stood in the way of progress.

From what has been said it may be seen that whilst there is yet a large virgin field for the employment of sulphate of ammonia in agriculture, many uses for ammonia are opening out, whilst the competition of nitrate of soda is only felt by sulphate. We have also seen that the increase in the production of ammonia is likely to suffer a check in the gas industry, but, on the other hand, blast furnaces and coke-ovens, as well as the shale-works, will probably pour it into the market in increasing quantities. The latter, however, are more subject to trade fluctuations than are the gasworks, so that we cannot help being impressed by the conviction that great variations will be seen in the sulphate of ammonia market in the future as in the past, that the present depression is only temporary, and that we can hopefully look forward to better times.

THE AMOUNT OF AIR CONTAINED IN WATER.

BY J. M. C. PATON.

(This Journal, 1896, 419.)

DISCUSSION.

The CHAIRMAN hoped that other members had been more fortunate than he in his search for results of experiments to enable him to reply to the questions put by Mr. Paton

(p. 420). Mr. Caven had already given the chief points known on the subject of the gases dissolved in water, and indeed the note itself was a better reply to some of the questions than much that might be said. It might, however, be of interest in this connection to call attention to the

J. C. THRESH'S APPARATUS FOR COLLECTING THE GASES DISSOLVED IN WATER.

a, flask filled with the water to be examined; *c*, filled with mercury by raising *e*; *f*, mercury trough; *g*, receiver for the gases as they come from *a*.

form of apparatus designed by J. C. Thresh for collecting the gases dissolved in water whilst engaged in the analyses of the Buxton Thermal waters, which would be found illustrated in the *Journal of the Chemical Society*, Vol. XXXIX., p. 399.

Mr. G. J. WARD said he had no experimental evidence to offer. Possibly to look at the question from a purely theoretical point of view would be the best, because it seemed to him that the amount varied so much that it was difficult to get at it exactly by experiment. He understood that Mr. Caven showed that the amount dissolved by water of gases found in the ordinary atmosphere came altogether to 3.12 vols. per 100 vols. of water at a temperature of 0° C. and 760 mm. pressure. Assuming the vacuum of an air-pump to be equal to 76 mm. pressure, the equivalent of about 3 ins. of mercury, the result in such a case would be that the amount of gas dissolved in the water would be one-tenth of what it was originally, *i.e.* 2.8 vols. of gas would be given off leaving 0.32 in the water. But those 2.8 vols. of gas then given off would now be under a pressure of only one-tenth of what they were in the first instance, and the result would be that they would occupy 28 vols. per 100 vols. of water used. That was taking no account of temperature. He found Bunsen gave the following figures as to the effect of temperature:—The absorption coefficient of nitrogen at 0° C. is 0.02035, at 5° it is 0.01794, at 10° 0.01607, at 15° 0.01478, and at 20° 0.01403. In the case of oxygen the coefficients were—at 0° C. 0.01114, at 5° 0.009628, at 10° 0.008250, at 15° 0.00789, and at 20° 0.007838. Carbonic acid gas varied in the same way but to a larger extent, the coefficients being at 0° 1.7967, at 5° 1.4497, at 10° 1.1847, at 15° 1.0020, and at 20° 0.9014. That meant that if cold water, instead of being at a temperature of zero, be taken at 15° C., which was what they might take it to be on an average, the absorption coefficients came very nearly to three-quarters of what they were at 0°. Therefore the gas dissolved in the water would be about three-quarters of the amount given above, that was to say it would be 2.34 vols. per 100 vols. of water. The amount left in the water after the reduction of pressure to one-tenth would come to a little over 0.2 vols. per 100, and the other 2.1 vols. would be given off. At the reduced pressure this would become 21 or 22. In addition to that they had to consider the effect of temperature. The temperature of water which gave a vapour tension of 3 ins. of mercury was, roughly speaking, 45° C. That would cause an expansion approximately of one-sixth, bringing the 21 or 22 vols. to 24 or 25. All those figures were based on the assumption that the water in the first instance was pure water and thoroughly saturated. The next question to consider was whether the water was likely to be saturated. As to the rate of diffusion of gas in liquid, he was sorry to say he had not got any exact figures. The rate of diffusion of gas in a liquid was inversely in proportion to the square root of

the specific gravity of the gas. That would account for the fact that the oxygen and nitrogen in water more nearly approached the theoretical quantity than did carbonic acid gas, which would diffuse more slowly. The effect of different solids in solution was, for ordinary waters, very small. The absorption coefficients for solutions of sodium chloride and sodium sulphate were only slightly less than pure water, but certain solids, such as normal sodium carbonate and sodium phosphates, and some organic sodium solids, absorbed, probably chemically, more carbonic acid gas. Whether that gas would be given off on heating to temperature of the air-pump, he could not say, but in a similar case of ammonia, which was dissolved in nitrate of potassium, it was entirely given up on boiling; so he would be inclined to say that the same would be the result with carbonic acid gas. Buchanan measured the solubility of carbonic acid gas in solutions of calcium and magnesium sulphates, which would be similar to the water in those districts; but the results varied according to whether the solutions were freshly prepared or old, and the effects produced by these salts were very slight. It seemed to him that they could take it that pure drinking water, containing the solids which it would naturally contain, only,—the solids found in strata—and which had not been heated to any great temperature, in a natural stream gradually trickling down, must contain, if not quite so, very nearly the theoretical quantity of gas dissolved. As to the effect of sewage, perhaps somebody present, who had made analyses of drinking waters and determined the manner in which they would absorb oxygen, would give some information on the subject. He had made one small experiment which anybody could make. Take an ordinary glass of soda water and try the effect of sugar and salt, which were of about equal solubility. The sugar would cause effervescence immediately; the salt comparatively slowly.

Dr. CLOWES said that Mr. Paton had given an average statement which would apply to all classes of water approximately, and the statement being an average one, might be taken as a rule for working. He (Dr. Clowes) however thought that different samples of water would have to be dealt with separately was the only solution of the problem. As regards the effect of sewage on dissolved gases in water, he had many years ago occasion to examine into that question. Sewage did assist in removing free dissolved oxygen from the water, the oxygen, as soon as it was absorbed producing oxidation of certain matter in the sewage. Hence, waters which were contaminated with recent sewage to any considerable extent were free from dissolved oxygen, in fact the proportion of oxygen which was found in solution in water might serve to decide whether there had recently been sewage in it or not. If no dissolved oxygen was found the water was probably badly contaminated with sewage.

Mr. L. ARCHBUTT suggested to Mr. Paton that it was rather unfortunate to describe the gases dissolved in water as air, because as far as the oxygen and nitrogen alone were concerned the gases dissolved contained roughly one-third of oxygen. But the proportion of dissolved carbon dioxide was probably always greater than that contained in air, and often very much greater. The amount would depend upon the proportion of dissolved carbonates of lime and magnesia. The latter salt holds the carbonic acid very loosely, for he had proved by experiment that water containing magnesium carbonate dissolved in a solution of carbonic acid could have all the carbon dioxide in excess of that required to saturate the magnesia expelled at the ordinary temperature and pressure by merely passing through the water a current of air free from carbon dioxide. The greater part of the magnesium carbonate was precipitated, and at the end of this experiment the magnesia and carbonic acid remaining in solution were in the ratio $MgO:CO_2$. Therefore, in an air-pump and at the temperature of the condenser very likely a good deal of the carbon dioxide might be given up from such water which would not be re-dissolved from the air in the cooling apparatus.

Mr. PATON after dealing with other points said that when the source of water was an underground supply, the quantity of gases contained was frequently more than that which was theoretically to be expected. If the mixture was under

pressure a considerable time the water held gas longer after release. If they took natural aerated waters for drinking purposes, and artificial ones, they would find that the natural waters would hold gas longer. Apparently there was not much on record to throw light on the main question.

SESSION 1896-97.

Jan. 28th, 1897.—Dr. S. G. Rawson. "On the Quantitative and Qualitative Separation of Ba, Sr, and Ca," and "On the Qualitative Separation of Bi, Sb, and As."

Meeting held on Monday, November 30th, 1896.

MR. T. FAIRLEY IN THE CHAIR.

NOTE ON AN EXACT METHOD FOR ESTIMATING THE INTENSITY OF THE X RAYS.

COMMUNICATED BY MR. F. W. BRANSON.

For comparing different sources of the X rays, the hand placed upon an ordinary fluorescent screen of barium platino-cyanide is a convenient test; but if an exact record is desired, a photographic process is necessary.

The following method, which I have devised, seems quite free from error:—

A quadrant of aluminium is taken, with millimetre steps (1—10). This is superimposed on a photographic plate, which is enclosed in a light-tight envelope, a vacuum tube is placed at a standard distance from the sensitive film, and an exposure of definite duration is given.

Development with a standard developer at a temperature of 60° F. for five minutes will reveal a number of steps on the negative, that number being exactly proportionate to the intensity of the X rays.

Comparative tests can thus be made with different vacuum tubes, or with the same tube under different conditions.

Mr. Branson then demonstrated the production and properties of the Röntgen rays by means of various apparatus, including the Wimshurst electrical machine, and exhibited a large number of photographs taken by these rays.

In answer to an inquiry as to whether any photographs had been taken by means of the Wimshurst machine, Mr. Branson stated that it was quite practicable, but that the time of exposure necessary was much greater than with a good induction coil, the minimum with the machine exhibited being about 20 minutes, whilst 1 minute sufficed with a coil which gave a 10-in. spark. This was accounted for by the great difference in intensity, which might be overcome by increasing the number of plates, and consequently the quantity of the discharge.

Mr. Branson considered that the use of the Wimshurst machine as a means of generating the X rays was capable of application to many commercial enterprises on account of its simplicity and adaptability to driving by mechanical means.

The use of the X rays in the examination of alloys was spoken of, and their application to the examination of food-stuffs, &c. for mineral impurities was perfectly feasible.

Mr. BROADBENT asked whether Mr. Branson had attempted to differentiate between the X rays, as it was supposed that they existed in two or three forms.

Mr. BRANSON, in reply, stated that the result of recent experiments had been, not to find two or three varieties merely, but a regular gradation of rays, as in the case of light.

SOME APPLICATIONS AND MODIFICATIONS OF THE MERCERISING PROCESS.

COMMUNICATED BY A. G. PERKIN, F.R.S.E.

PROFESSOR HUMMEL, who is unavoidably absent this evening, has asked me to bring before your notice some specimens of fabrics treated by somewhat novel processes, which are based upon the old and well-known method of "mercerisation." It appeared probable that these samples, which have been recently presented to the Dyeing Department of the Yorkshire College, would be of interest to the members of this Section.

The original process of Mercer consists in treating calico with a solution of strong caustic soda (40—50° Tw.) at the ordinary temperature, the material being by this means considerably strengthened, and also acquiring an increased attraction for colouring matters. As a process preliminary to dyeing, it has been but little utilised on account of the excessive contraction which the cotton undergoes (about $\frac{1}{2}$ th in length and breadth). Strange to say, this contraction, which in the early days was regarded as a defect, has proved to be a valuable feature, capable of useful application; thus in recent years it has been employed by printers for the imitation on calico of the "crêpons" introduced by the woollen manufacturers. For this purpose the cotton is printed with a solution of gum, usually in the form of stripes, and, after drying, passed through the caustic alkaline solution, with the result that the unprinted portions contract while those parts protected by the gum do not, and hence the latter assume the characteristic puckered or "crêpon" appearance.

More recently still, a French inventor has discovered that wool and silk, which are injuriously acted upon by caustic alkali at the ordinary temperature, are practically unattacked at 0° C. by this agent, though cotton, on the other hand, is still mercerised. By treating, therefore, mixed fabrics consisting of silk and cotton, or wool and cotton, with the caustic soda solution at this low temperature, the cotton is contracted while the wool and silk remain unaltered, and the local contraction thus produced causes the beautiful wave-like "crêpon" effects on the patterns now before you. Excellent imitations of "crêpon" work of a slightly different character are produced by mercerising in this way double cloths having a woollen face and gauze-like cotton back, interwoven at certain points in accordance with the pattern desired.

The most novel process here illustrated, which is the subject of a French patent, is based upon the contraction which silk is found to undergo when treated with dilute sulphuric acid. The following particulars, taken from the *Färber Zeitung* (VII., 139), are said to be employed:—They consist in steeping the material in sulphuric acid 75—80° Tw., at a temperature of 15—37° C., for 5—15 minutes, and though the silk thus suffers a loss of lustre, its strength is practically unaffected. By printing the silk with a wax resist, certain portions of the fabric may be protected from the action of the acid, and various ruffled "crêpon" effects are thus obtained, as seen in the samples submitted to your notice.

Finally, I have to bring before you a novel and somewhat ingenious adaptation of the process of mercerisation, which consists in the treatment of cotton with strong caustic soda solution, means being at the same time, however, employed to prevent the contraction of the material. Owing to the strain thus brought to bear upon the fibres during the mercerising process, and therefore while they are still in a plastic condition, they acquire such a high lustre as to give the material the appearance of silk.

Dyed and undyed samples of Lehner's artificial silk produced from collodion are also submitted to your inspection.

DISCUSSION.

The CHAIRMAN inquired whether artificial silk was made in this country.

Mr. J. W. PROCTER asked whether the sulphuric acid used in the process of mercerisation did not affect the durability of the silk fibres.

Mr. PERKIN, in reply, stated that artificial silk is not made in this country, but principally in France. The nature of the colouring matter of the silk is not stated. In some cases it has been introduced into the collodion mass before drawing into fibres. It had not been found that the sulphuric acid had any deleterious effect on the fibres.

NOTE ON THE DURABILITY OF PLATINUM-IRIDIUM VESSELS IN LABORATORY USE.

BY T. FAIRLEY.

Mr. FAIRLEY showed vessels of the alloy of platinum with 10 per cent. of iridium, which had been in everyday use for over 14 years. This alloy is much harder and more durable than pure platinum, and if carefully used does not crack, as has been recently stated by Mr. Blair, chief chemist in one of the United States Government laboratories. Even pure platinum vessels are sometimes injured by the sudden application of a powerful blow-pipe flame to the cold metal. The author also referred to the advantage of keeping platinum vessels thoroughly clean by carefully rubbing them after each heating with water-worn sand, free from any angular or gritty particles.

Some years ago Mr. Casamajor drew attention to this fact, and proved that vessels so treated lost much less in weight after repeated heatings than if they had not been cleaned at all. The action of gas or other flames containing carbon compounds tends to disintegrate the metal—by the formation and decomposition of carbon compounds of platinum—so that it becomes porous or even loosely coherent. The rounded sand acts as a burnisher, and mechanically restores the surface of the metal when rubbed on it.

The green flames given by certain burners in which an explosive mixture is burnt, act on platinum much less than other forms of Bunsen burner.

The author had also paid attention to the shape of platinum vessels in relation to durability. A shape more or less hemispherical appears to be the best in this respect. Sharp corners should be avoided.

DISCUSSION.

Mr. W. McD. MACKEY inquired as to the effect of fusions with strong alkalis on the platinum-iridium vessels.

Mr. FAIRLEY said that it was not so marked as in the case of platinum vessels, but undoubtedly a better substitute for such purposes would be platinum vessels coated with gold. The price of the alloy was about 2s. 6d. per oz. more than that of pure platinum, and as to the question of the comparative loss in weight, it had been found that the loss in the case of the vessels made of the alloy was about one-half that of vessels made of pure platinum.

Mr. Fairley also described a laboratory apparatus for supplying distilled water, heating drying-closet and steam bath, and supplying steam for distillations or other purposes.

The special points about the apparatus are the very efficient means used for minimising the loss of heat from the gas consumed, and a simple form of two-way tap, by which the steam may be directed as required.

The author hopes to describe this apparatus more fully later.

DR. JOHN CLARK IN THE CHAIR.

ESTIMATION OF NICKEL AND ZINC AS PHOSPHATE.

BY JOHN CLARK, PH.D.

IN 1883 I pointed out how cobalt could be conveniently separated from nickel as ammonio-phosphate of cobalt by a modification of Dirrell's process, and this method has been described by the late Professor Dittmar in his work on quantitative chemical analysis as the most elegant of all the known processes for the estimation of cobalt; and, according to Hope (this Journal, 1890, 375), it has been in daily use in a works for several years, and has given complete satisfaction both as to accuracy and the facility with which the separation can be made. Professor Dittmar also proved, by experiments, that this method was suitable as a supplement to the nitrite method for bringing the cobalt of the Fisher's salt into a weighable form.

After the removal of the cobalt as ammonio-phosphate, the nickel in the solution is either deposited by electrolysis, as recommended by Hope, or thrown down as sulphide with the object of getting rid of the phosphoric acid, and subsequently precipitating it as oxide with caustic soda; but, on account of the difficulty of removing the alkali, this latter method generally gives high results.

The nickel in the solution can be obtained as phosphate by protracted boiling, but this operation is so very troublesome, on account of the tendency to bumping and the difficulty of precipitating the whole of the nickel, that, so far as I am aware, no one has recommended this as a means of estimating nickel. I have found that this difficulty can be overcome by adding dilute HCl to the cold or moderately warm liquid till the solution is neutral to test paper, and stirring, when the nickel separates out as a pale green crystalline precipitate of ammonio-phosphate of nickel, which, when dried over sulphuric acid, has the composition $\text{NiNH}_4\text{PO}_4 + 6\text{H}_2\text{O}$. When dried at 100°C . it loses rather more than 5 atoms of water, and becomes yellow; but I have not been able to drive off the whole of the water at this temperature. When ignited, it is converted into pyrophosphate of nickel, which is brown in colour, and difficultly soluble in acid when ignited at a high temperature.

The ammonio-phosphate of nickel obtained in this way is slightly soluble in water, and, on this account, the filtrate contains a little nickel, but the amount seldom exceeds 3 mgrms. per 100 c.c. This can be precipitated as sulphide, and weighed either as oxide or sulphate, but the necessity of doing this can be obviated by the addition of alcohol, which brings down practically the whole of the nickel as ammonio-phosphate, and when the precipitate is washed with cold water containing alcohol, the filtrate gives only a faint indication of nickel.

To test the accuracy of this process, known quantities of pure nickel in the form of chloride were mixed with 10 times their weight of phosphate of ammonia and more than sufficient HCl to form a double salt; heated to boiling, excess of ammonia added, and cooled. To the ammoniacal liquid dilute HCl was then added from a burette till the blue colour disappeared and the liquid became green, when the HCl was added cautiously, stirring after each addition, till the liquid was practically neutral to test paper. The nickel begins to separate out while the liquid is still alkaline, and provided a sufficient quantity of phosphate of ammonia is present, the precipitation is complete before the liquid is quite neutral to test paper. About 20 per cent. of alcohol was then added, and the precipitate allowed to settle and stand for several hours, when it was filtered off, washed with cold water containing about 10 per cent. of alcohol, and dried. The precipitate was then removed from the filter, which was ignited first, the precipitate afterwards added, and weighed as pyrophosphate.

Ni taken.	Weight of Pyrophosphate.	Ni found.	Ni per Cent.
Grms.	Grms.	Grms.	Grms.
0.1000	0.2485	0.0098	99.80
0.1517	0.3780	0.1510	99.54
0.3076	0.7700	0.5080	100.13

The process which I have described is not suitable for the estimation of nickel in presence of cobalt or zinc, but it can be made available for the estimation of nickel in presence of cobalt by a simple modification.

New Method of separating Nickel and Cobalt.

In separating nickel and cobalt by Dirvell's process, the cobalt is precipitated as ammonio-phosphate, and the nickel is left in solution, provided the cobalt exists in the cobaltous state, but when the cobalt is in a higher state of oxidation no cobalt separates out as ammonio-phosphate, and this fact can be utilised for the precipitation of nickel in presence of cobalt.

For this purpose the solution of nickel and cobalt, in the form of chlorides, is mixed with 10 times as much phosphate of ammonia as the combined metals, and heated for a few minutes with HCl and a considerable excess of bromine. The solution is then supersaturated with ammonia, while free bromine is still present, and heated with some peroxide of hydrogen to ensure the complete oxidation of the cobalt. The ammoniacal liquid is then cooled, neutralised with dilute HCl, as already described, and stirred, when the nickel will be precipitated as ammonio-phosphate, and the cobalt will remain in solution. About 20 per cent. of alcohol is added, to complete the precipitation of the nickel, and after standing for several hours, the precipitate is filtered off, washed with dilute alcohol, dried, ignited, and weighed as pyrophosphate. When the proportion of cobalt is small, the nickel precipitate should be quite free from cobalt; but when there is any considerable quantity present, a little cobalt salt is apt to separate out on standing, and may not be completely removed by washing. In such cases it is advisable to redissolve the nickel precipitate in HCl before ignition, and reprecipitate it after oxidation and addition of some phosphate of ammonia, when the nickel should be obtained quite pure. The cobalt in the filtrate is precipitated as sulphide, and converted into phosphate.

This process is specially suitable for the separation of nickel from small quantities of cobalt. It is generally admitted that it is impossible to separate cobalt and nickel by the nitrite method when there is only 1 part of cobalt to 50 or 100 of nickel; and, according to Herrenschildt and Capelle (Zeit. Anal. Chem. 32, 607), the cyanide method, when carried out as directed by Fresenius, leaves something to be desired. By the method which I have described, there is no difficulty in detecting and estimating a minute quantity of cobalt, even when it is accompanied by 200 times its weight of nickel, and after the separation of the nickel, the presence of 1 mgrm. of cobalt communicates a decided rose tint to 200 c.c. solution.

In each case a trace of nickel was found in the filtrate from the cobalt phosphate.

Probably the best existing method for the detection and separation of a minute quantity of cobalt in presence of a considerable quantity of nickel without concentration with hypochlorite, as recommended by Fleitmann (Zeit. Anal. Chem. 14, 76), is the nitroso- β -naphthol process of Ilinski and Knorre (Zeit. Anal. Chem. 24, 595); and the experiments which I have made seem to indicate that the method which I have described is at least quite as delicate.

Ilinski and Knorre recommend that the nickel should be estimated by difference or by evaporating the filtrate to dryness, igniting, dissolving in nitric acid, and precipitating with KHO; but, in my opinion, the nickel in the filtrate can be much more conveniently estimated as phosphate, and when oxidised with bromine and peroxide of hydrogen any cobalt not precipitated by the nitroso- β -naphthol will be found in the filtrate from the nickel, and can be precipitated as sulphide.

Estimation of Zinc as Phosphate.

In 1871, Hugo Tamm (Chem. News, XXIV., 148) introduced a method of estimating zinc depending on the precipitation of the metal as ammonio-phosphate. For this purpose he supersaturated the zinc solution with ammonia, then rendered it slightly acid with HCl, and to the hot liquid added phosphate of soda, which brought down the zinc as a voluminous precipitate of phosphate of zinc, which, when kept for a few minutes near the boiling point, combines with phosphate of ammonia and comes down as a dense white precipitate, which, when dried at 100° C., has the composition ZnNH_4PO_4 , and is converted into pyrophosphate by ignition. According to Tamm, the defects of the process are: that the phosphate of zinc is not quite insoluble, and that it adheres firmly to the side of the flask in which the precipitation takes place; and he further points out that as some of the zinc is volatilised on ignition, it is better to weigh the precipitate as ammonio-phosphate. The defects referred to by Tamm can be overcome by the method which I have described for nickel. The ammoniacal zinc solution, containing sufficient chloride of ammonium to form a double salt, is mixed with 10 parts of phosphate of ammonia for each part of metal, and to the cold, or moderately warm liquid dilute HCl is added from a burette, till the solution is neutral to litmus paper. The zinc comes down at first as a flocculent precipitate, which becomes crystalline on stirring as the liquid is neutralised.

The precipitate, which is easily removed from the sides of the vessel, after standing for several hours, is thrown upon a filter and washed with cold water till it is completely free from salts of ammonia. When dried over sulphuric acid or in a water-bath, the precipitate has the composition ZnNH_4PO_4 , and can be weighed without ignition; but it is not necessary to collect it on a weighed filter, as there is no loss of zinc when the precipitate is removed from the filter and ignited apart from the paper.

In applying this method to zinc ores the iron, alumina, and manganese are removed by means of ammoniacal peroxide of hydrogen, and to the hot alkaline liquid, solution of carbonate of ammonia is added to precipitate the lime. The whole of the lime is not removed in this way, but

when the phosphate of ammonia is added, the small quantity remaining is precipitated as phosphate and is quite free from zinc.

When the percentage of lime in the ore is small the addition of carbonate of ammonia may be dispensed with, but when phosphate of ammonia is added to an ammoniacal zinc solution containing a considerable quantity of lime, a portion of the zinc is carried down along with the phosphate of lime. After getting rid of the lime the solution is set aside to allow the magnesia to separate out as ammonio-phosphate, and the zinc is precipitated in the filtrate by neutralising with dilute HCl, as already described.

This process is not suitable for the estimation of zinc in presence of nickel, cobalt, or copper, but it is a convenient and accurate method of estimating zinc in an ammoniacal solution, without the necessity of separating the zinc as sulphide.

DETERMINATION OF ALUMINA AND OXIDE OF IRON IN MINERAL PHOSPHATES, MANURES, SULPHATE OF ALUMINA, ALUM, &c.

BY R. T. THOMSON, F.R.C.

THE determination of alumina and oxide of iron by precipitation as phosphate is one of those methods of analysis which have been dealt with by various chemists, but there still remains an element of unsatisfactoriness about all the published processes. This is due to the fact that all the conditions which may tend to cause inaccuracy are not taken into account, and while one condition of obtaining correct results is carefully elaborated, another and perhaps equally important one is altogether neglected. In a paper which I read to this Society nearly 11 years ago, I endeavoured to bring out these points, and the present paper is simply a continuation, or the second part, of the former one, giving the result of experience gained since then.

Taking, in the first instance, the estimation of alumina and oxide of iron in mineral phosphates and manures, we must view the matter from two standpoints. The first of these is how to obtain the precipitated phosphates of alumina and iron free from phosphate of calcium, and the second is how to obtain and keep the precipitate in the perfectly normal state.

As usually practised the direct estimation of alumina and oxide of iron in the solution of mineral phosphates is carried out by precipitation (after preliminary neutralisation) in a hot solution with acetate of ammonia containing a considerable excess of free acetic acid. Anyone who has carried out this process with careful observation, will have noticed in many cases the crystalline precipitate of the less acid phosphate of calcium which is formed when the mixture is heated to only 60° C., as directed by Gladding in his recent paper on this subject. To get rid of all the lime, Gladding recommends a second and even a third reprecipitation of the phosphates of alumina and iron, and certainly not less than that is required in the circumstances to obtain anything like a pure precipitate. From the result of experiments I have made, it is evident that the acetate of ammonia is the agent which makes the decomposition of the di-acid phosphate of calcium take place with greater facility than would otherwise be the case. This is made plain by the fact that when a solution of phosphate of calcium in hydrochloric acid is made neutral to methyl orange or lacmoid, it shows little tendency to decomposition at 60° C., although when brought nearer the boiling point there is very considerable decomposition. At lower temperatures than 60° C. the acetate of ammonia causes precipitation in the di-acid phosphate of calcium solutions, and even in the cold there is often such precipitation, especially in presence of the phosphate of iron and alumina. In the neutralised solution, however, there is no tendency to decomposition in the cold, or even up to a temperature of 50° C., and I have therefore come to the conclusion that the neutralisation method I proposed formerly, has very decided advantages over the acetate of ammonia process, although this question was left unsettled in the first part of this paper (see this Journal for 1886, page 152). This latter

process consists in adding ammonia to the cold solution of the mineral phosphate or manure until it is neutral or only faintly acid to lacmoid paper, when the whole of the aluminium and iron phosphates will be precipitated, and all the phosphate of calcium will remain in solution. Of course it is necessary to agitate well after each addition of ammonia in order to redissolve any phosphate of calcium precipitated locally, but even with ordinary care I have found that no lime is precipitated. It may be interesting to note that slight traces of free phosphoric acid left in solution do not hold any weighable quantity of alumina or iron in solution, and this has been conclusively proved by experiments which were made to find the amount of standard alkali consumed between the point at which the slightest trace of permanent precipitate of phosphate of iron and alumina was formed, and that at which the solution was found to be neutral to methyl orange or lacmoid paper. From these results I have calculated that, under the conditions of the method of analysis, 1 part by weight of aluminium phosphate requires 3 parts by weight of phosphoric acid (H_3PO_4) to keep it in solution, and that 1 part of ferric phosphate requires no less than 12 parts of phosphoric acid for the same purpose. It will thus be apparent that traces of this acid left free, can have practically no effect on the determination of alumina, but more especially on that of iron, while the freedom of the precipitate from phosphate of calcium will be thus insured.

We come now to the second point which must be attended to in the endeavour to secure correct results, namely, how to obtain and keep the phosphates of iron and aluminium in the normal condition. In my former paper I showed that at least 1.5 times the proportion of phosphoric acid theoretically required, must be present, in order to precipitate alumina and oxide of iron as normal phosphates; otherwise, the precipitates are more or less basic, and their composition cannot be depended on. But although this may be attended to, as Gladding for instance does, the end thus accomplished is destroyed by his washing with dilute acetate of ammonia, which indeed keeps the precipitate in a suitable gelatinous condition, but decomposes it by dissolving out some of the phosphoric acid in combination with the alumina or oxide of iron, and thus rendering the precipitate basic. That this decomposition took place with dilute acetate of ammonia, and also with cold and hot water, I showed in Part I. of this paper and in a contribution to the *Chemical News* (vol. 54, page 252) on the Estimation of Aluminium in Iron and Steel. These facts as regards water-washing of ferric phosphate have, I am glad to find, been corroborated by Mr. R. M. Caven (this Journal for 1896, page 17), who discovered them quite independently. I have found that, even with moderate washing, alumina may be 8 per cent. and oxide of iron 5 per cent. too low, calculating on 100 per cent. of these substances present. Now this attending to the keeping of the precipitates in the normal condition is altogether omitted in descriptions of methods of analysis for the determination of alumina and oxide of iron in mineral phosphates and manures, and of aluminium in iron and steel. The plan I formerly gave for this object is entirely successful, and consists (after a slight alteration) in washing with a 1 per cent. solution of nitrate of ammonium containing 0.2 gm. of di-acid phosphate of ammonium ($NH_4H_2PO_4$) per litre. Of course part at least of the phosphoric acid in this will remain in the precipitate, but from further experiments it appears quite clearly that it cannot interfere materially with the weight of the phosphates, especially when it is considered that part of the phosphoric acid must go to supply what the water would otherwise carry away. A phosphate of alumina precipitate, when washed and drained, retains about 35 times, and a phosphate of iron precipitate holds about 30 times its own weight of water or the nitrate and phosphate of ammonia solution, but all the phosphate of ammonia in the latter cannot raise the percentage of alumina more than 0.13 per cent., or the oxide of iron more than 0.36 per cent., calculating on 100 per cent. of these oxides. It may just be further noted that washing with water alone, or water containing 0.2 gm. per litre of phosphate of ammonia, brings the precipitate into a slimy condition, which is avoided by the addition of a per cent.

or so of a neutral salt of ammonia. That nitrate of ammonia is best is obvious, while the acetate is decidedly objectionable, for reasons referred to in dealing with the precipitation of the phosphates of alumina and iron in order to free them from lime.

In the above remarks I have confined my attention to the removal of phosphate of calcium from the phosphate of alumina and iron precipitate, but there is often fluoride of calcium present in mineral phosphate, and this dissolves in hydrochloric acid, and is precipitated, partially at least, by both the acetate of ammonia and the neutralisation methods. The possible interference of fluoride of calcium was suggested to me by Dr. Clark when I wrote the first part of this paper, in which it was proposed that the fluorine might be got rid of by a preliminary treatment with sulphuric acid. This, however, would form a large quantity of comparatively insoluble sulphate of calcium, which should be avoided if at all possible. Since then I have found that evaporation of the hydrochloric acid solution of the phosphate to dryness with nitric acid, has the desired effect of removing all the fluorine, and thus this interfering agent is easily eliminated.

We have now seen how the determination of alumina and oxide of iron is beset with difficulties, but these can be dealt with in detail as already described, and, bearing these in mind, a fairly accurate method may now be described. From 3 to 5 grms. of the sample are dissolved in hydrochloric acid, filtered, 20 c.c. or so of nitric acid added, and the mixture evaporated to dryness, by which the fluorides are removed. The reason for not adding the nitric acid to the unfiltered solution, is with the object of keeping out iron existing as pyrites, which, as Mr. Shepherd has shown, is left unaffected when mineral phosphates are made into superphosphate, and they should therefore be stated separately from the oxide of iron. The dry residue is now dissolved in hydrochloric acid, diluted with cold water to about 200 c.c., and neutralised with ammonia, adding a little methyl orange to the solution to serve as a rough guide as to when the neutral point is nearly reached, then finishing off carefully with delicate blue litmus paper as indicator, and leaving the mixture to the faintly acid side. The phosphates of alumina and iron thus precipitated are now washed with a 1 per cent. solution of nitrate of ammonia, containing 0.2 grm. of di-acid ammonium phosphate per litre, until no lime is detected by oxalate of ammonium in the washings. The precipitate is now dried, ignited thoroughly, weighed, dissolved in hydrochloric acid, the iron estimated by the bichromate process, and the alumina and oxide of iron deduced from the weight of the mixed phosphate precipitate and the proportion of iron found. If it is thought advisable, the precipitate may be dissolved before ignition, some phosphate of ammonium added to supply the requisite excess of phosphoric acid, and the precipitation, &c. carried out precisely as described. It should be mentioned that the solution of di-acid ammonium phosphate used for washing should be made exactly neutral to methyl orange with dilute solution of phosphoric acid, as the article as purchased usually contains a little of the mono-acid phosphate, which would of course cause a slight precipitation of phosphate of calcium during the washing of the precipitate.

The above process may be applied with advantage to the estimation of alumina in sulphate of alumina and alum, as lime, magnesia, and other bases are not carried down with the same ease as when alumina is precipitated simply with ammonia.

I may just add that the neutralisation process serves for the perfect separation of alumina and oxide of iron from cobalt and nickel, zinc and manganese, as well as lime and magnesia; all of these metals remaining completely in solution under the circumstances.

DISCUSSION.

The CHAIRMAN referred to the disadvantages attendant on the estimation of iron and alumina as phosphate, as usually carried out, and expressed his pleasure at the satisfactory manner in which the author had succeeded in preventing the formation of basic phosphates, and in insuring the absence of phosphate and fluoride of calcium from the precipitate.

GOLD MILLING AT BALLARAT.

HAMILTON M. WINGATE, B.Sc., F.C.S., M.A.M.E.

GOLD was first discovered at Ballarat in August 1851, and, during the 20 years following, mining of the precious metal was almost exclusively confined to the shallow and deep leads formed by the denudation of the surrounding Silurian rocks, which had concentrated the gold into these ancient river beds and creeks.

In the year 1856 this field alone produced gold to the value of 3,750,000*l.*, and up to the present time the total yield of the Ballarat district has been upwards of 65,000,000*l.*

When the alluvial leads were becoming exhausted, attention was turned to the quartz veins which abound, and at the present day mining in the immediate vicinity of Ballarat is almost entirely confined to them. The quartz reefs are low grade; 6.16 dwt. per ton was the average of last year's returns for the Ballarat district, and owing to their poorness and the unsystematic methods of working, but few are remunerative.

The reefs consist essentially of free-milling quartz with but little mineral, which consists principally of iron pyrites, with a small percentage of galena, and sometimes, but rarely, a little zinc blende, and these for the most part are not intimately associated with the gold. The gold is of high quality, and often very coarse.

In America and South Africa statistics of the cost of milling, &c. are carefully kept; but in Victoria, on the other hand, it is almost impossible to get accurate information, and what is published is only approximate, so this induces me to lay before the Society the following statistics, which are the results of the past quarter's milling, ending September 30th, 1896, at the Grey Horse Gold Mine, which is typical of the district, and which were taken by me during a temporary residence at Ballarat, and under my personal supervision.

At this mine the quartz is mostly of a friable nature, intermixed with chlorite and other slate, containing about 2 per cent. of pyrites, and carrying 4 to 7 dwt. of gold per ton.

The ore, on being delivered at the mill, is tipped over "grizzlies," spaced so that all pieces under 1½ ins. fall into the ore bins, while the larger pieces are broken to the required size by two Blake-Marsden rock crushers.

The mill contains 40 head of stamps, each having a falling weight of 915 lb., and dropping 6 ins. 90 times per minute, which are fed automatically.

The discharge is low—about 2 ins. Owing to the coarseness of the gold, the screens adopted have 144 round punched holes per sq. in. The diameter of these holes is 0.048 in. The screens overhang at an angle of 11°.

No inside plates are used, but mercury is fed into the mortar boxes every two hours.

Outside the mortars the crushed ore is discharged on to a lip plate, and then passes over three copper plates 5 ft. wide, each 2 ft. long. They weigh 5 lb. per sq. ft. The lip plate and first plate yield the most gold; little is got on the second, the third serving to catch any loose mercury which always carries with it in small quantities.

After passing over the copper plates, the tailings are allowed to escape, not being sufficiently rich to attempt further treatment, their gold contents then only averaging 23 grains per ton, and but 37.6 grains of mercury per ton is lost.

The plates are dressed with a weak solution of cyanide of potassium and mercury every eight hours, and skimmed daily, and the whole mill is cleaned up every four weeks.

During the quarter, 5,480 tons of ore were crushed for a total yield of 1,342 oz. of gold, being an average of 4.89 dwt. of gold per ton.

The gold caught in the mortar boxes amounted to 70 per cent. of the total, while the plates yielded the remaining 30 per cent. The amalgam of the mortar boxes yielded 65 per cent. of gold, that of the plates 33 per cent.

The gold averages 982 fineness, the mint value being 4*l.* 3*s.* 5½*d.* per oz.

The mill is supplied with power from two Babcock and Wilcox water boilers, which drive a compound condensing

engine, and wood is used for fuel. The whole building is fitted with incandescent electric lights.

The following are the tabulated statistics of cost of milling for quarter :—

Cost of Milling at the "Gray Horse Mine," Ballarat, 40 Head of Stamps.		Quarter ending Sept. 30th, 1896.	
Tons crushed		5,480	
Labour	s. d.	0 8 810	
Firewood		0 6 611	
Shoes and dies		0 1 770	
Screens		0 0 377	
Mercury		0 0 013	
Stores and various expenses		0 1 314	
Total cost per ton of ore of 2,240 lb. ..		1 6 895	

The crushing capacity of the mill during this period was 3 tons per stamp per 24 hours.

The tons are of 2,240 lb., as in Australia; the short ton of 2,000 lb. adopted in America and South Africa is not used.

Owing to insufficiency of ore during the quarter, the mill was only run for 16 hours per day, which of course increased the cost of milling, owing to watchmen having to be provided, loss of time, waste of fuel, &c.

I may add that during this time the cost of mining and transport to mill, exclusive of development work, amounted to 8s. 10 35d. per ton.

The temperature of the water in the supply dam averaged 44° F., it being winter, and this is rather low for obtaining good amalgamation.

The following is the result of sizing and assaying a sample of the tailings taken as they left the tables during ore crushing. The yield of this crushing was 7.07 dwt. per ton; the assay of the tailings was 23 grains per ton, which shows the extraction to have been 88 per cent. of the total gold.

Sieve Mesh.		Proportion of Sample.	Assay in Grains.	Proportion of Total Gold.
Through.	On.			
..	40	Per Cent.	Per Ton.	Per Cent.
..	40	10.65	24	11.11
40	60	17.02	26	19.99
60	100	19.00	20	16.52
100	..	50.05	24	52.22
Loss		3.28	..	0.16
Total		100.00	..	100.00

This result showed that the bulk of the gold in the tailings was in an excessively fine state of division, and that the tailings were unadapted for profitable concentration.

Concentration was tried with canvas strakes, and a sample of concentrates thus obtained assayed 1.14 oz. of gold to the ton, and contained 65 per cent. of iron pyrites, the remaining 35 per cent. being silica.

The following results of sizing and assaying these concentrates may be of interest, from the fact it discloses that nearly 40 per cent. of the gold saved in them passed the 100-mesh sieve.

Sieve Mesh.		Proportion of Sample.	Assay in Oz.	Proportion of Total Gold.
Through.	On.			
..	50	Per Cent.	Per Ton.	Per Cent.
..	50	10.77	0.80	7.55
50	40	8.35	1.10	8.05
10	50	10.25	1.00	8.99
50	60	17.80	1.05	16.33
60	80	6.05	0.80	4.21
80	100	27.10	0.60	11.42
100	..	18.15	2.50	39.80
Loss		1.23	..	0.66
Total		100.00	..	100.00

In the Ballarat East Mines the pyrites is very low grade, and only rough concentration is attempted, and that by hand. In the Western mines the mineral carries more gold, and there percussion tables are used, besides blanket strakes, &c. Fine vanners were erected on one mine, but have been discarded.

The milling of the ore on this field as a general rule is very faulty. Hand feeding is still in vogue, and the consequent irregularity in the quantity of ore delivered into the mortar boxes and the uneven distribution seriously affect both the amalgamation and the crushing capacity of the mill.

In construction, the mortar boxes are simply designed as crushing machines. Inside, amalgamation is nowhere attempted, though it appears to me to be especially suitable for this district.

In many mills mercury is not fed into the mortar boxes, while mercury riffles, and in some cases simply iron riffle tables, take the place of the usual copper plates.

Where concentration is carried on, the resulting mineral is sold to the local chlorination works. Treatment of the tailings in bulk by means of the cyanide process has, as yet, been unsuccessful, owing to their small gold contents and the unsuitable condition of the gold.

DISCUSSION.

The CHAIRMAN commented on the fact that the cyanide process could not be successfully applied to the tailings, and remarked that this was possibly due to the presence of copper pyrites, which would interfere with the economical extraction of a small quantity of gold by this process.

MR. ALFRED JAMES expressed his pleasure at hearing such a paper at one of their meetings. Although it was outside the usual type of paper read before the Society, yet it must be remembered that the subject dealt with was not nearly so foreign to the object and aims of the Society as might at first sight appear to be the case. There was, in reality, quite a considerable number of the members of the Society of Chemical Industry who were professionally employed on gold mills and reduction plant, as any member would realise if he looked through the monthly list of changes of address published in the Journal.

He had been particularly interested in hearing of the latest returns from Ballarat, as that district was scarcely regarded as an exponent of the best up-to-date milling practice. He remembered, when visiting the district some time since, remarking to a manager on the entire absence of rock breakers, automatic feeders, and other labour-saving appliances, and being met with the rejoinder that the shareholders' sons were most deserving young men, and he would back them against any rock breaker or ore feeder in existence. He noted that such a prejudice was now becoming a thing of the past, and that at the mill under review Blake-Marsden crushers were in regular use, and he expected that Fine vanners would also be adopted as soon as "the deserving young men" had become more accustomed to the machine.

With regard to the Chairman's remarks on the amount of gold still left in the tailings, he might add that this matter had been engaging the special attention of the Department of Mines of the colony, and he had received an official report on the subject. He suggested that the reason for the non-adoption of the cyanide process was the extremely low value of the tailings and the fact that the coarse crushing prevalent throughout the district did not permit the fine gold locked up in a grain of coarse sand to be sufficiently exposed to the solvent powers of the cyanide solution, but that the increased local attention now being paid to the subject might be reasonably expected to overcome this difficulty and lead to the adoption of this Glasgow process.

Meeting held on Friday, November 20th, 1896.

MR. R. C. WOODCOCK IN THE CHAIR.

THE DEATH OF MR. A. H. MASON.

MR. WOODCOCK said that owing to the unavoidable absence of the Chairman he had somewhat suddenly been called upon to take his place, and equally suddenly had heard of the lamented death of the previous Chairman of the Section, Mr. Alfred H. Mason. He thought that a few words reviewing Mr. Mason's connection with that branch of the Society would not be amiss. They might remember that they were called together in May 1894 by Mr. McGeorge to meet at the Ashland House, when he brought forward a suggestion that, as there were so many members belonging to the Society in America, they might form an American Section. At the meeting among others was Mr. Mason, and from that moment he devoted much time and energy to the Section, and helped in every way possible. Even those who were not connected with him on the Committee could not fail to appreciate the admirable way he filled the chair, and the interest that he took in every detail connected with the subjects brought before them: but he was certain that at the Committee meetings there was no man who was more energetic, who was more willing to take on the onerous duties—and they were onerous at the commencement of this Section of the Society—before they had any regular monthly meetings at all. Mr. Mason was always the first to help; and indeed it was owing to his energy throughout that they had become the successful branch of the Society which they undoubtedly were that day. He was sure that they all felt very deeply the loss that they had sustained by his sudden death; and, furthermore, that it would be the wish of all that a resolution should be passed expressing the deep regret and sympathy that they felt for his family in their bereavement.

MR. JAS. HARTFORD said that it was with profound regret he rose to move that the Secretary be requested to write a letter to Mrs. Mason, and convey to her the sincere regrets of the Section. To him Mr. Mason was an old friend, and his death was a sudden blow. He had no idea that Mr. Mason was even seriously ill; and the Society met with a very serious loss in his death, because nobody could take a greater interest than he did in his work. At all times he had the thoughts of the Society in his mind, and he spared no time or trouble to make the meetings and every thing connected with them very successful.

DR. H. ENDEMANN seconded the resolution, which was put and carried unanimously.

THE ANALYSIS OF ASPHALT.

BY H. ENDEMANN, Ph.D.

THE greater activity existing in the cities throughout the United States with regard to asphalt paving has also been

the cause of a greater activity amongst chemists, with the object in view to aid the practical man in the selection of raw material by so-called chemical analyses. New methods of analysis have been proposed, and in addition thereto the results of such have been discussed, and even have been the foundation for theoretical speculations of more than doubtful utility. Altogether our experimental work on asphalt is not extended enough for theorising. Theorising upon insufficient knowledge can only hurt the cause of scientific investigation, for the reason that it causes prejudice. I refer here especially to such views as were expressed by Messrs. Sabin and Mabery in the Journal of the American Chemical Society for 1896, pages 279—283.

The original investigations and analyses of asphalt, which were made in the early part of this century, had shown that the bituminous part thereof consisted of two radically different substances or classes of substances: the first a volatile and distillable portion consisting of hydrocarbons, and the second a non-distillable compound containing, besides carbon and hydrogen, over 14 per cent. of oxygen.

These substances had been called by Boussingault respectively petroleum and asphaltene, the latter name being reserved for the substance containing oxygen and occurring in asphalts in largest quantity.

If we look at our modern literature on this subject, we again meet the same names "petroleum and asphaltene," but find that the separation of these substances is undertaken by new methods; and as far as the analytical results are concerned we find the ratio of petroleum to asphaltene reversed, inasmuch as the petroleum is the predominant portion. I have not been able to find any valid reason why the products of such separation should be given the names of substances analysed minutely and to a certain extent characterised and classified. The new methods referred to have either originated with Mr. Clifford Richardson, formerly in the employ of the Government at Washington and now with the Barber Asphalt Paving Co., or they have been adopted by him for his extensive investigations. They are described in Sadler's Handbook on Industrial Organic Chemistry, 1895, page 42, as also by many or most writers upon this subject in unchanged or slightly modified form (L. A. Linton), and consist mainly in a successive extraction of the material by petroleum ether and subsequently such other solvents as spirits of turpentine, chloroform, and bisulphide of carbon; the substance extracted by petroleum ether being called petroleum.

These new methods have nothing to recommend them to the chemist except ease of execution, though conscientious chemists must find it hard to account for some anomalies, of which, as far as I could see, none of the investigators and method-promoters speak.

Asphalt may be looked upon as a solution of asphaltene in petroleum. If we add to such mixture petroleum ether the petroleum proper dissolves, but with it a goodly portion of asphaltene, which is easily soluble in a concentrated solution of petroleum in petroleum ether. After allowing this first solution to run off through a filter, fresh petroleum ether is poured on the asphalt, and this treatment continued as long as the solution appears coloured. But if these fractional extracts be mixed, a precipitate invariably forms, for the reason that asphaltene is less soluble in a dilute solution of petroleum in petroleum ether. That this is really the cause of the precipitate can be verified. Treat asphalt with some petroleum ether, then filter, and add to the clear solution petroleum ether. A precipitate will form, which is brought upon a filter and tested with petroleum ether for solubility. It shows the characteristics of asphaltene. There will then be chemists who, during an analysis, will look upon this turbidity as a separation due to change of temperature or spontaneous evaporation of the volatile petroleum ether, and thus will count the precipitate with the petroleum. Others will think that the filter was at fault, allowing suspended matter to pass through, and will refilter, counting the precipitate with the asphaltene. Who shall in such cases decide in the absence of specific instructions? for the method is an arbitrary one, and instructions must be therefore more specific. The actual knowledge of the facts

stated above was the cause that I had such precipitates re-filtered and counted as asphaltene, at the peril of obtaining results differing from those obtained by others or so-called authorities.

Analyses made by others as well as myself by these methods showed so little of a relation to the usefulness or applicability of the asphalts, that for a long while I considered chemical analysis of asphalts merely as a costly toy, *i.e.*, as something entirely useless, but for which people are willing to pay.

I had to admit and do admit that the analysis as carried out by these later methods suffices to make identity or non-identity of two samples probable or highly probable; it also is adapted to watch the supply of a single mine or the refining of asphalt from the same source; but it does not admit of basing any conclusions upon the results, if we work on asphalts from different sources.

I will illustrate this by considering refined asphalts from different sources. If asphalts are refined, they are melted at a high temperature, either in order to allow of subsidence of coarser mineral impurities, or simply to obtain a more uniform product, or also to allow of the escape of the most volatile petroleums, whose presence is not useful for paving, because on exposure they will soon be lost by evaporation, and leave a more brittle compound behind. The temperature generally applied is about 450° F.

One would think, now, that the resulting asphalts, aside of the mineral constituents, should show a certain similarity, if such asphalts were analysed as are acknowledged to give satisfactory pavements after their composition is rectified in the usual manner, or that the additions could be added directly from the results of the analyses. This, however, is not so.

Three analyses of Trinidad land asphalt, Trinidad lake asphalt, and Mexican asphalts, all refined, had given on analysis by the extraction method the following results:—

	Trinidad.		Mexican.
	Land.	Lake.	
Soluble in petroleum ether, called petroleum.	24.97	31.86	87.12
Asphaltene	33.37	28.12	10.19
Insoluble and ash	41.33	40.01	2.69
Ash	34.13	30.08	0.27
Organic	7.20	6.33	2.42

If, for instance, for the manufacture of an asphalt cement from land asphalt we use for 100 of the refined asphalt 20 of residuum oil for the production of the asphalt cement used for the paving mixture, and we count the residuum oil all as petroleum, while the refined Mexican asphalt were used without any addition, the proportions of petroleum to asphaltene in these would appear as follows:—

	Trinidad Land Asphalt Cement.	Proportion.	Mexican refined.	Proportion.
Petroleum	44.97	1½	87.12	8½
Asphaltene	33.37	1	10.19	1

If we consider the composition of asphalt cement from Trinidad lake asphalt, where less residuum oil is used, we get about the same proportions as in the Trinidad land asphalt. If the analyses were correct, one would have to argue that the substances composing these asphalts must differ completely, notwithstanding the fact that in other properties there is such great resemblance. Hence, various tests were made to ascertain, if possible, properties wherein the products of one analysis differed from those of another. So it was found that the petroleum obtained by petroleum

ether, when dissolved in carbon tetrachloride, absorbed iodine. The iodine numbers were found as follows:—

	Trinidad.		Mexican.
	Land.	Lake.	
Iodine absorbed in 20 hours.	20.32	19.04	21.90

The action was in all cases accompanied by a precipitation. There was no hydroiodic acid formed, hence there was addition and not substitution.

Bromine acted alike at first, but later much hydrobromic acid was formed, showing that addition was followed by substitution. Hence there was great similarity in these products. The iodine number for asphaltene was found very much greater. To avoid coming back to this subject again, I wish to add here that the iodine numbers above given pertain to the asphaltene in the petroleum as it is obtained by petroleum ether extraction.

The question whether asphaltene is not soluble even in dilute solutions of petroleum in petroleum ether, had not been touched as yet, and, if so, how much asphaltene will go into such solution, required investigation. To get an approximate idea I took extracted petroleum obtained from refined asphalts and removed the easily volatile portion first by heating in an air-bath at 220° C. for two hours. The residue was then powdered and extracted by petroleum ether, and the residue from such extraction was weighed:—

	Grams.
Petroleum by extraction method weighed	1.916
Volatile at 220° within two hours	0.037
Residue from petroleum ether extract	0.859
In petroleum ether extract by difference	0.420

Since this latter extract is known to contain both petroleum and asphaltene, its quantity is to be divided. For want of anything better I divided it in the proportion of volatile petroleum to insoluble asphaltene obtained. Thus we find that the petroleum obtained by extraction with petroleum ether contains:—

	Per Cent.
Petroleum volatilised	33.27
Petroleum in extract calculated	9.36
Total	42.63
Asphaltene as insoluble residue	44.83
Asphaltene in extract calculated	12.54
Total	57.37

According to this, what has been called petroleum in the extraction analysis contains only about 43 per cent. petroleum proper.

The above analyses, if calculated upon this approximate determination, would become:—

	Trinidad.		Mexican.
	Lake.	Land.	
Petroleum	13.70	10.74	37.45
Asphaltene	16.28	47.70	59.85

I believe no one accustomed to the figures generally reported for these three excellent asphalts would recognise them in this shape. It should be borne in mind that these tests were all made on refined asphalts, *i.e.*, such as had been kept in the melted state for some time, whereby the more volatile substances had been lost; that, therefore, they possessed a similarity not to be expected in crude asphalts, where such an averaging as to results would certainly lead us considerably more astray than might be possible in these cases.

If we look back upon Boussingault's original investigations on the asphalt of Pechelbrunn we meet at once some

difficulty, inasmuch as his statements are not all verified by the publication. The pure bitumen of this asphalt had given on analysis—

	Per Cent.
Carbon.....	85.90
Hydrogen.....	11.25
Oxygen.....	2.85

From this he had obtained, by distillation, petroleum with—

	Per Cent.
Carbon.....	87.15
Hydrogen.....	12.28

and, after prolonged heating as residue, asphaltene with—

	Per Cent.
Carbon.....	74.23
Hydrogen.....	9.90
Oxygen.....	15.87

If the asphaltene were not the product of an oxidising process—by no means improbable,—this asphalt must contain less than 20 per cent. of asphaltene, which is in contradiction to his other statement, that asphaltene is the predominant constituent of asphalt bitumen. In the hope of understanding the questions involved better, the following experiments were made.

Mexican refined asphalt was extracted repeatedly with warm petroleum ether, the residue taken up in chloroform, and, after evaporation of the latter, dried and analysed.

0.190 so-called asphaltene gave
0.0031 ashes, hence

0.1569 organic, which yielded

0.4815 CO₂ × 0.1196 H₂O.

	Per Cent.
Carbon.....	84.20
Hydrogen.....	8.52
Oxygen.....	7.28

Examination of some of the material showed that it was not free from petroleum, giving, by further treatment with petroleum ether, solutions which left a sticky residue.

The quantity of oxygen in this asphaltene is only about half of what Boussingault gave in his publication, but the quantity of extract with petroleum ether was not so much as to make it at all possible by further extraction to enhance the quantity of oxygen to such figures as should be expected from Boussingault's statement.

There are now two possibilities: either asphaltene from Bechelbroun asphalt has a different composition from asphaltene from Mexican asphalt, or the Boussingault asphaltene is an oxidised asphaltene as nature provides it.

The first of these questions I have, so far, not been able to decide, for the reason that I have no Bechelbroun asphalt in my possession. But, comparing asphaltenes from other asphalts with the first, it might be possible to ascertain whether asphaltenes of such entirely different composition exist, and, if not, experiment might decide if asphaltene is capable of further oxidation, *i.e.*, accumulation of oxygen.

In order to ascertain similarity or dissimilarity of matter in asphalts from other sources, I analysed asphaltene obtained from refined Trinidad lake asphalt after purifying the same by repeated extraction with hot petroleum ether, dissolving it then in chloroform, filtering, and evaporating to dryness. The extraction with petroleum ether had been carried to the end in this case, *i.e.*, until but traces were taken up by petroleum ether.

The material thus obtained contained 9.27 per cent. of ashes, mainly sesquioxide of iron. This latter must have been in combination with asphaltene, from the fact that it is soluble in chloroform, 0.0884 grm. of this substance giving 0.0082 ashes gave 0.6708 water × 0.2492 CO₂.

For calculation we have to calculate from above data the actual quantity of organic substance taken. The ashes, consisting of Fe₂O₃, contain 0.0057 Fe, which will have to be subtracted from the quantity of material weighed off for analysis, while an equivalent quantity of hydrogen will have

to be added = 0.0002 grm. Thus we find that the organic matter really used for analysis weighed 0.0829 grm. We have therefore in this case—

C.....	81.97
H.....	9.49
O.....	8.54

I take occasion to here point out the fact, generally overlooked, that refined asphalts always give an asphaltene rich in mineral matter, which is soluble in chloroform and other similar solvents. In analysing refined asphalts or asphalt pavements it is therefore not safe to call the loss of a sample in weight, when it is washed with chloroform, either asphaltene or bitumen.

To get to these substances, incineration of the asphaltene thus obtained is required in order to determine the quantity of inorganic matter contained therein. While the results of elementary analyses of asphaltene make it quite probable that the quantity of oxygen contained in asphaltene is not so high as given by Boussingault, it was left for me to show yet, that asphaltene is really able to acquire more oxygen by exposure to air. The Mexican asphalt, which I had examined, was found to contain so little of impurities, that I concluded, for the purpose of obtaining further light on the question desired to elucidate, to operate directly on this.

Two portions of refined Mexican asphalt were heated in an air-bath, side by side, to a temperature ranging between 225° and 250° C. The one sample was thus heated in the open air of the bath, while the other was enclosed in a tube through which a current of carbon dioxide gas was passed.

The heating was continued for 29 hours, with intermissions to allow the weighing of the samples. In both cases the boats containing the samples lost in weight rapidly at first, then slower, and finally the boat heated in air gained in weight considerably; the surface of this lost its smooth appearance and became apparently covered with a skin similar to that observed on hot milk. The sample dried in carbonic acid gas kept its smooth surface. The following is the record:—

0.2567 heated in air to 225°—250° for 29 hours weighed 0.1987.

0.2745 heated in CO₂ to 225°—250° for 29 hours weighed 0.2018.

Heated in air, 77.3 per cent. were left.

Heated in CO₂, 73.5 per cent. were left.

In order to now ascertain whether the greater weight of sample heated in air was due to absorbed oxygen or to insufficient loss of petroleum, elementary analyses of the residuums were made:—

1. Asphalt heated in air.....	0.1987
Gave ashes.....	0.0063
Organic.....	0.1924
Per Cent.	
Gave 0.5675 CO ₂	80.44 C
0.1152 H ₂ O.....	8.35 H
	11.18 O
2.—Asphalt heated in CO ₂	0.2018
Gave ashes.....	0.0028
Organic.....	0.1990
Per Cent.	
Gave 0.6000 CO ₂	82.21 C
0.1637 H ₂ O.....	9.18 H
	8.31 O

Thus it was ascertained that asphaltene is able to take up oxygen, and it becomes now probable that what Boussingault called asphaltene, and which was obtained by him by heating asphaltic bitumen for 50 hours in air, was a substance really not pre-formed in asphalt, but produced during the process.

As a check on the above an elementary analysis of untreated, refined Mexican asphalt was made:—

0.1451 grm. of this gave

Ashes 0.0032 grm.

Leaving 0.1419 grm. organic, which yielded

0.4332 CO ₂	Per Cent. 83.26 C
0.1377 H ₂ O.....	10.78 H
	5.96 O

Mexican asphalt was found to yield (heated in CO_2)—

	Per Cent.
Petroleum	26.8
Asphaltene	73.2
100 asphaltene thus obtained contained	Per Cent.
73.2 " would contain	8.31 O
Oxygen found	6.08 O
	5.96

These 73.2 per cent. asphaltene require—

	Per Cent.
C	60.18
H	6.94
O	6.08

The whole asphalt contained—

	Per Cent.
C	83.26
H	10.78

now deducting the above from these figures leaves for petroleum—

	Proportion
C 23.08 : 12 = 1.92	1 of $\text{C}_{13}\text{H}_{18}\text{O}$
H 3.84 : 1 = 3.84	2 of $\text{C}_{13}\text{H}_{20}$

The asphaltene would be approximately $\text{C}_{13}\text{H}_{18}\text{O}$, or a multiple.

While the formula for asphaltene is verified by direct analyses, that of petroleum is deduced from a mixture, and may require verification. Petroleum also includes a series of compounds, while asphaltene appears as a single body. It differs from the substance called asphaltene by Boussingault by containing less oxygen. The largest quantity of oxygen which up to this time I had been able to accumulate in asphaltene was 11.18 per cent., as the result of 29 hours' heating in air, but without stirring or other means to aid oxidation.

The fact that air-stirred paving mixtures give with chloroform an extract which contains considerable lime, made it probable that oxidation might be accelerated by the addition of lime. In fact, I found that thus the limit of 11.18 per cent. O could be exceeded.

By heating asphalt (Mexican) in air with lime, only 19.6 per cent. could be driven off. Analysis of the resulting substance proved that it was not petroleum remaining, but oxygen absorbed by asphaltene, which had brought about this result.

It was then tried to free the lime compound from lime by boiling with hydrochloric acid for a long time, but this proved impracticable owing to the utter insolubility of the lime compound. After a day's treatment still 6 per cent. of lime remained.

Inasmuch as there was a considerable difficulty of obtaining either the free acid or even the neutral lime salt in this manner pure enough for analysis, a combustion was made of a chloroform extract, which, however, contained also some lime. Calculated for the free compound, I found C, 78.75 per cent.

Owing to the difficulties encountered in this direction, I again oxidised the Mexican asphaltene without lime, but care was taken to carry the oxidation further than done heretofore. At first the skin was removed frequently, and after all had become solid the mass was brought into a mortar and finely pulverised, then brought back into the air-bath, and this repeated until the mass even at 230° C. was perfectly dry. The substance which then remained was black, insoluble in chloroform, but soluble in soda. From the solution in soda it is precipitated by acids as a brown precipitate.

The asphaltene according to these tests has therefore disappeared, and an acid body has formed which I will call asphaltic acid, and which, as far as oxygen is concerned, resembles Boussingault's asphaltene:—

1. 0.1531 gave 0.0898 H_2O and 0.4352 CO_2
2. 0.157 gave 0.0907 H_2O and 0.4466 CO_2

this body containing therefore:—

	1.	2.	Calculated for $\text{C}_{20}\text{H}_{20}\text{O}_4$
Carbon	77.53	77.58	77.61
Hydrogen	6.51	6.41	6.46
Oxygen	15.96	16.01	15.93

The existence of this body makes the formula for asphaltene $\text{C}_{20}\text{H}_{20}\text{O}_4$ probable. According to my observations the petroleues have not shared in the reactions, but behaved like inert bodies throughout. Whether the organic substance adhering to the mineral part of many asphalts, which is insoluble in the ordinary solvents, is asphaltic acid or a salt thereof, has, so far, not yet been determined.

Great stress is laid by some writers upon the fact that, using spirits of turpentine for dissolving asphaltene, only a partial extraction of the bitumen is obtained, and that chloroform will then dissolve another part; and from this it is argued that what is called asphaltene consists really of two different substances.

If we extract petroleum with petroleum ether we obtain a dissolved mixture of petroleum and asphaltene, but the residue is by no means free from petroleum. It requires heat and many extractions to remove all the petroleum, and the analysis prescribes the use of cold petroleum ether. Hence we operate upon a mixture of petroleum and asphaltene again. Of such mixture the hot spirits of turpentine dissolve the petroleum and so much asphaltene as is soluble in a solution of petroleum in spirits of turpentine. But the solvent fails as soon as all petroleum is gone.

This is easily illustrated by extracting asphalt with hot spirits of turpentine under addition of a little petroleum. There remains under these circumstances nothing upon the filter for chloroform to dissolve.

Inasmuch as I have shown in this paper the shortcomings of the ordinary methods of analysis, I should not close it without recommendations as to a rational method of analysis based upon my investigations, though the method is really self-evident from the nature of the results obtained.

Analysis.—For refined asphalts I propose the following manipulations:—

Five grms. of refined asphalt are treated with chloroform, and the residue is collected on a weighed filter and treated in the ordinary manner, as, for instance, described by Linton. The chloroform solution is then distilled from a weighed flask, and residue in flask dried at 120° for half an hour. In order to get this residue into a flask as small as possible, it is proposed to feed the chloroform solution gradually into the flask through a stop-cock funnel while the distillation proceeds.

About 0.2 to 0.3 gm. of the residue—or more if greater accuracy is aimed at—are then brought into a porcelain boat and heated in a current of CO_2 for 12 hours at a temperature of 250° C. To aid volatilisation the asphalt should be spread over as large a surface as possible.

Loss, petroleum; residue, asphaltene and ash.

Of the latter an elementary analysis can be made, if desired.

The drying tube for the reception of the boat is closed at the end by an asbestos stopper. The narrow vertical end of tube connects with a cylinder containing liquid CO_2 . The current is regulated by means of a H_2SO_4 wash-bottle. In the case of such asphalts as contain very much mineral matter, more than 5 grms. should be taken. Crude and rich asphalts should be refined on a small scale and in strict imitation to the process as conducted on a large scale.

The loss noted during this operation should be called water and light petroleues. The residue is then analysed as above. Not less than 200 grms. should be taken for this process. If, during refining, much mineral matter should subside, the ratio thus removed should be determined by separate determinations of the mineral matter in the crude and refined, and calculated under proper considera-

tion of the concentration of the material during the process, if it be not desirable to keep up the uniformity of the mixture by stirring. The vessel for refining should be a casserole with straight, perpendicular sides, about twice as deep as wide, and should be filled to about half. The end temperature for the refining process may range from (350°—450° F.) 175° C. to 235° C., according to the application for the asphalt in view. After ascertaining loss during the process, some of the material is poured out and cooled quickly.

It appears from this investigation that asphalt is mainly asphaltene, which is a solid body, and which is softened by the presence of a lesser quality of petroleum, somewhat like turpentine, which is rosier softened by spirits of turpentine (17 to 19 per cent.). Whether asphaltic acid is present or not in natural asphalts is possible, but I look upon its presence as a deterioration, and in refined asphalt mainly due to faulty treatment.

In conclusion I will here put side by side the results of the analysis of Mexican refined asphalt by the old and by the method which I have described above:—

	Old Method.	Proposed Method.
Petroleum.....	87.12	26.51
Asphaltene.....	10.19	70.80
Inorganic.....	0.27	0.27
Organic, not bituminous.....	2.42	2.42

According to my method the ratio of petroleum to asphaltene in this asphalt is 1:2.7. The ratio in Trinidad asphalts with 60 per cent. bitumen ranges from 1:5 to 1:7. If we desire to make of our Mexican refined asphalt a hard asphalt with proportion of 1:7, we learn that we must reduce this Mexican asphalt by 16 per cent. by evaporation. On the other hand, if we desire to soften asphalts with ratio 1:5 or 1:7 to ratio 1:2.7, we know that we will have to add residuum oil in proportions of 8 to 12 for 100—60 per cent. asphalt.

In practice we use, however, more residuum oil, for the reason that these oils are not quite so heavy as the petroleums of refined asphalts, hence are more apt to disappear during the manufacture of the asphalt cement, especially if air-current stirring is resorted to. Such simple ratios, which at the same time are practically true, cannot be deduced from the old-style analysis.

It would naturally be a drawback for my proposed method of analysis if it were either difficult as to manipulation or if it would require a considerable time for execution. I take, therefore, occasion to state that the time is not more than that required for the old method, and that in fact it requires less manipulation, and certainly so as regards the amount of available information.

The examinations as to the composition of asphaltene have so far only included the Mexican asphalt and the Trinidad asphalts, and in these cases it has been found that the asphaltene in all of these was identical. Whether the asphaltene of other asphalts may have a composition different from the one here described remains to be seen. At present I am not able to make positive statement as to this. I have, however, very little doubt but that the asphaltenes will be found either identical or isomeric compounds of the one described. Boussingault's figures for his mistaken asphaltene are really nearer my own for asphaltic acid than appears on the face of the records. Even 35 years ago chemists were frequently satisfied with analyses giving the carbon $\frac{1}{2}$ per cent. less, and the hydrogen $\frac{1}{2}$ per cent. higher than calculation demanded. The analyses of Boussingault were made over 60 years ago.

I have been asked whether it would not be possible to recalculate the many analyses of especially crude asphalts made during the last years to avoid the loss of so much labour. To this I have to answer that it is not possible, for the reason that the higher petroleums, when dissolved in petroleum ether, exert a greater dissolving influence upon asphaltene than the lower.

However, as regards refined paving asphalts, an approximation is possible, and may be reached by dividing the petroleum found according to old-style analysis by $3\frac{1}{2}$. This will give us real petroleum. The difference between this figure and the original is to be added to the asphaltene.

I hereby take occasion to thank my assistant, Mr. John W. Paisley, for the help which I have derived from his industry in the course of this investigation.

DISCUSSION.

The CHAIRMAN said that very little had been written on the subject of asphalt, and the information, so far as he was aware, that had been published was very unreliable and meagre. It was particularly interesting to see the enormous change in the composition of asphalt that Dr. Endemann's method of analysis gave compared to the former ones. He hoped that Dr. Endemann would continue his investigations, and favour them with his further researches on other specimens. He remembered inquiring what became of a lot of old asphalt piled up in front of his place of business, and he was informed it was impossible to work it over again. It might have been from want of knowledge in using the stuff, and he would like to ask Dr. Endemann why it was impossible to use this asphalt over a second time after it has once been laid down.

Another interesting point was the fact that the chloroform extract should take out so much mineral matter. Most chemists would hardly be prepared to find such a great deal of mineral matter in a chloroform extract. He should be glad to hear from Dr. Endemann as to the quantity of mineral matter that he had found in it. He presumed it was in organic combination.

Dr. H. SCHWEITZER said that since acetone and ethyl ether had also been recommended for the extraction of petroleum in the old scheme of asphalt analysis, he would like to ask Dr. Endemann whether he noticed the same difficulties experienced with petroleum ether when working with these other solvents, and whether petroleum also remained undissolved and mixed with asphaltene in the insoluble residue; and further, whether he thought that the mineral matter in the chloroform solution was present in the shape of a lime salt of the substance called by him asphaltic acid.

Dr. H. ENDEMANN said in reply that there was a lime salt of asphaltic acid, but he found it to be insoluble in chloroform. He had shown that if you dissolved in these asphalts one substance, you might get a certain portion of another in a solution. While the lime salt had never been obtained in solution by itself, its solubility in chloroform was due perhaps to the presence of a certain quantity of asphaltene.

As to the re-working of the asphalt, this of course would depend entirely upon the cause of the difficulty. If the difficulty had resulted from exposing the asphalt to too high a temperature the asphalt would be lost. He did not think there would be an easy way, applicable on a manufacturing scale, of reducing the asphaltic acid again to asphaltene.

As far as the other solvents were concerned he had made no experiments, but concluded that, inasmuch as it was not claimed for these other solvents that there was any remarkable difference in the results, they probably did act in the same way. For instance, if they had said we prefer acetone or we prefer alcohol for the extraction of the petroleum, because the results would be entirely different from the others, then he thought it might be worth while to examine; but since they did not claim that the relation between petroleum and asphaltene, if separated by any modified method, produced entirely different results from those of the method here investigated, he expected that the same difficulty would exist in these proposed methods.

Dr. SCHWEITZER said that, according to Sadtler, acetone was a much better solvent than petroleum ether, and he (the speaker) came to the same conclusion from his analyses of asphalts. He once extracted the petroleum with acetone, which he had always used because it is so much easier to work with. He extracted the sample of asphalt cold and when the acetone was perfectly colourless. To see how it

would work he heated the acetone; he did not notice any further solution.

Dr. ENDEMAUN said that if the acetone extract were coloured, it was a sign that it took up brown asphaltene, because petroleums have been described by all the original investigators as light yellow oils. The best information on the original literature of asphalts was to be found in Dumas' Applied Chemistry, in the 7th volume, where elementary analyses as well as other so-called analyses were compiled. For instance, in many cases destructive distillation of asphalt, giving quantities of gas, water, oil, and coke obtained, was called an analysis. Such were many analyses met with in works written in the early part of the century. Amongst the analyses he found those of Boussingault.

Mr. F. J. SCHMIDT asked if Dr. Endemaun had any experience with so-called gilsonite.

Dr. ENDEMAUN said he had not. He intended to take other asphalts by-and-by, and test them to see how the asphaltene of those other substances compared with the asphaltene which he had been able to obtain from the Trinidad and the Mexican asphalts. He had taken the matter up only about two months before, and had not gone so very deeply into it, except as regarded those asphalts which were now on the market and generally applied for paving. For these he had elaborated his method of analysis and given his reasons for the proposed changes.

ON CRUDE AND REFINED CARBONATE OF POTASH.

By C. F. A. MUSEL.

THE U.S. Tariff Act of 1894 has on the free list a paragraph which reads and is punctuated as follows:—"Potash, crude, carbonate of, or 'black salts.' Caustic of potash, &c., &c."

The importers' claim, at the time this matter was brought to the attention of the U.S. laboratory, was that all carbonate of potash imported should be entitled to free entry under this paragraph. The examiners who handled this article claimed that certain grades of carbonate of potash were dutiable, and to support their claim forwarded to us a number of samples, with the request that we state whether, in our opinion, they were crude or refined.

Any chemist I think will recognise the difficulty which presented itself, rendered more important as several million dollars' worth of goods were involved; and it was only after the examination of a large number of samples that the idea of distinguishing between crude and refined carbonate as hereafter set forth occurred to me.

As the matter has turned out, the importers' protest was sustained by the U.S. Board of General Appraisers, thus losing interest for us; but I believe the collector has appealed from this decision, and it may be reversed by the Court.

It is my understanding that the question to be decided is the distinction between crude and refined carbonate of potash, potash, or potassium carbonate, as I believe these various terms may be used interchangeably.

In my opinion, from a chemical standpoint, it is impossible to say that because a certain sample contains a relatively high percentage of potassium carbonate it is refined, and that another sample containing a much lower percentage of potassium carbonate is for that reason crude. It is doubtless the case that any sample containing, as have the majority of samples examined by me up to date, over 90 per cent. of potassium carbonate, may very safely be termed refined or perhaps, more conservatively, partly refined.

They are not by any means chemically pure, but they certainly are not crude. Carbonate of potash, designated in chemistry by the formula K_2CO_3 plus one or more molecules of water, may be prepared in a number of different ways and from a number of different materials.

There is, I believe, but one process at the present time which is of any commercial importance or significance. In this process the potassium carbonate is prepared from potassium chloride or sulphate—enormous deposits of which exist at Stassfurt, Germany—by a process analogous in every respect to the well-known Leblanc soda process.

It will be readily seen that a number of intermediate products may be put on the market varying from the very crudest first product to the highest grade of refined carbonate of potash. It becomes almost impossible, therefore, to say what is refined carbonate of potash.

We may, however, state, I think, in a negative way, that a sample is *not crude*; as, in my opinion (from the definition of the word *crude*), any product obtained from this by any process of refining whatever is certainly partially refined.

I have made no mention of the other processes which were formerly, and may still be, used to some extent. Without entering into such processes in detail, I will say that from whatever source the potassium sulphate or chloride is obtained and whatever process is used, carbonate of lime or limestone must be employed to convert the alkaline sulphate to the corresponding alkaline carbonate.

For this reason, lime in some form is always a constituent of crude potash, and crude potash also almost invariably contains a certain percentage of caustic potash.

It is my opinion, therefore, based on these facts, that all the samples I have examined, with the exception of the few reported as crude, are *partly refined* and the majority *highly refined*, or constituting what should be justly termed refined carbonate of potash.

DISCUSSION.

The CHAIRMAN said that the words as used the Government appeared to be for the purpose of fixing whether or no there should be any duty on this material; and if such were the case he supposed the word "refined," as applied to it, did not imply any particular percentage.

Dr. SNEDECOR, head chemist of U.S. laboratories, said that the appraisers had decided that they must regard refined carbonate of potash as dutiable. The contention of the importer was that all carbonate of potash, whether refined or crude, was free under the clause of the free list, which really made no distinction. According to the wording of the paragraph it would seem that carbonate of potash, if even chemically pure, was free, but the appraisers did not take that view of the matter. It was held that refined carbonate of potash should be dutiable under a general clause. It was put under the general paragraph providing for chemical salts with a duty of 25 per cent., because it was held that it could not be placed on the free list, since the free list did not mention refined carbonate of potash; but the free list did mention carbonate of potash, black salts, and several other things. If he was correctly informed, the case had been recently decided in favour of the importers, and was now on appeal before the Courts. It was really a commercial and a legal question rather than a chemical one, and the drawing of any distinction between the crude and refined article was a difficult point. He would not be prepared to say that because carbonate of potash contained 95 per cent. of carbonate that it was necessarily a refined article. It would be impracticable to draw any line of percentage in purity. It would be a question of process of manufacture—the amount of manipulation gone through. He thought that originally crude carbonate of potash was "black salts." They were mentioned in one of the previous tariffs, were prepared mostly in Canada, and thence imported into the States. Black salts would be crude carbonate of potash. Any advance beyond that state would possibly involve more or less of a refining process. In regard to asphalt, the law permitted asphalt to be considered as crude, although it has been melted, and much of the water evaporated, and much of the foreign impurities removed. It still remained crude asphalt.

Mr. E. HARTLEY said that the legal question involved was this. There had been a provision in the tariff for a number of years for potash on the free list, which read as follows:—"Potash, crude, carbonate of, or black salts," and caustic potash; and now that was amended in the last tariff so as to include caustic potash in sticks or rolls, all placed on the same footing. The question was, What was the interpretation? If crude carbonate of potash be synonymous with black salts, why was caustic potash in the high refined condition of sticks or rolls put upon the free list? It seemed also that the manufacture from black salts into potash directly was not now a matter of much

importance. Nearly all carbonate of potash came to the States, and was made by the Leblanc process from potassium chloride. The tariff was inadequate and out of date. The only proper course to take was to place all these products that were either inferior or equivalent to caustic potash in advancement on the free list.

Mr. C. F. A. MEISEL explained that the question was at present *sub judice*, and if the Courts decided the interpretation of that paragraph unfavourably to the importers' claim, the question would arise as to the distinction between crude and refined carbonate of potash. The opinion he wished to elicit, therefore, was as to whether it would be just to term any carbonate of potash that contained lime a crude carbonate of potash. There was an easy method of determining whether carbonate of potash contained lime or not. The test was simple and quick, and a distinction could easily be drawn between the importation that contained lime and the importation which did not. If the Courts finally decided that all forms of potash were free, the question would have no significance; but should they decide that they were not all to be free, it would become of considerable importance to have some quick and simple test to determine the difference.

Dr. H. ENDEMANN thought that the mere presence of a small quantity of carbonate of lime would be of very doubtful utility in that case.

Dr. SHERER asked where in that case they would put raw sugar, which had gone through a good many processes of manufacture and yet was a crude product. Could they still regard carbonate of potash as a crude article after it had gone through certain processes of manufacture?

Dr. ENDEMANN said that raw sugar implied manufactured sugar, and the mention of raw sugar in the tariff must include the permission to use all such processes as were necessary for the separation of this sugar from the liquid or juice, without, however, any additional steps. It was possible to have a raw product yet implying manufacture. The statute could not mean that cane or saccharine juice was raw sugar.

Dr. H. SCHWEITZER understood it to be the commercial usage which settled questions of this kind. If the imported article did the work of " K_2CO_3 ," then it was refined, no matter whether it contained 20 per cent. or 95 per cent. of " K_2CO_3 ." But if it contained impurities and had to undergo some process of refining before it was applied as " K_2CO_3 ," then it would be the "crude" product whatever percentage it contained.

Mr. MEISEL stated that the great bulk of potash imported contained over 95 per cent. of potassium carbonate.

Dr. M. ALSBERG said that if any process, more than the crudest manipulation, applied to any material, raised the material from the class of crude products, black salt would be a refined product. It was manufactured from wood ashes by means of caustic lime, and underwent a thorough process of lixiviation, evaporation, and manipulation. He had bought ashes which contained a higher percentage of alkali than the carbonate would call for. In other words, the process of causticisation had gone a great deal further than intended. If any process, which was more than the crudest manipulation, applied to any material, raised the material from the class of crude products, black salts would be condemned.

Mr. E. H. GANE said that this question might best be settled from the standpoint of the retail druggist. When a salesman sent in his order to his wholesale firm, if he wanted a refined article, all products which did not answer the test of the U.S. Pharmacopoeia were considered crude products.

Mr. E. A. SCHROEDER thought that imported carbonate of potash should be considered crude so long as it required any further refining on the part of the U.S. Moist bicarbonate of sodium, manufactured by the ammonia process, was imported as a crude article, whereas the substance only required drying to refine it. He thought that whether it was a refined article or not depended entirely upon the percentage of carbonate of potash present.

Dr. ALSBERG said that under those circumstances a crude potash did not exist. It was all refined.

Mr. C. F. A. MEISEL said in reply:—Take any process of manufacture. The object was the conversion of the

material from the form in which it existed in nature to the desired form. In the manufacture of carbonate of potash, the sulphate as a first step was converted into carbonate; that carbonate was impure, from being worked with other substances. Nevertheless they had accomplished the conversion of the natural salt into the salt desired. In practice the article went through without being taken out of the furnace.

It was a continuous process, but could be divided into a number of steps, and any article after the first step in the process was at least partly refined. Perhaps the only crude potash was the first material, which does not come on the market.

Dr. H. SCHWEITZER then read his paper, "Precaution in Reducing the Tinctorial Strength of Aniline Colours," in which he reported the formation of water insoluble substances in aniline colours to which cane sugar and bisulphate of sodium had been mixed for reducing purposes. The cane sugar had been decomposed by the action of the acid salt, and insoluble carbonaceous matter had been formed.

Meeting held on Friday, October 23rd, 1896.

DR. C. T. CHANDLER IN THE CHAIR.

THE MANUFACTURE OF ALKALI BY THE AMMONIA PROCESS, AND THE ALKALI TRADE OF THE UNITED STATES.

By J. A. BRADBURN.

THE history of the ammonia-soda process is well known to all who are directly interested in the manufacture of alkali, and more or less known to those in whose business soda is used; moreover, during the last three or four years a few works have been built in the United States to work this process. There is, however, still a large quantity of alkali products imported, so that there is yet plenty of room here for the growth of the manufacture of heavy chemicals. A history of this process has been given by L. Mond (*this Journal*, 1885, 52) and by A. Scheurer-Kestner (*Ibid.*, 1887, 322). The profitability of this industry is shown by the large dividends distributed by the largest ammonia-soda concern in England, and by the largest similar concern in the United States.

The following table, supplied by the Bureau of Statistics, Washington, D.C., gives the quantities and values of alkali products imported into the United States for the years given:—

Bleaching Powder.		Sal Soda.		Soda Ash.	
Quantities.	Values.	Quantities.	Values.	Quantities.	Values.
Lbs.	Dols.	Lbs.	Dols.	Lbs.	Dols.
1885 94,698,380	1,153,337	26,039,782	203,179	260,932,988	3,065,979
1886 98,016,208	1,354,019	30,687,608	197,249	279,331,320	3,229,050
1887 103,097,817	1,554,168	25,681,496	194,597	263,274,392	2,857,930
1888 101,699,978	1,672,130	25,048,475	154,111	267,896,710	2,681,793
1889 104,152,723	1,659,472	23,703,047	147,257	286,103,275	2,752,865
1890 89,111,312	1,385,080	31,680,469	257,147	290,141,652	2,245,001
1891 111,156,006	1,481,470	28,548,379	252,051	320,009,298	1,122,700
1892 116,796,147	1,840,056	22,509,306	226,522	329,880,894	1,282,416
1893 120,786,233	2,212,606	22,777,488	238,923	388,841,970	1,890,788
1894 81,610,063	1,507,076	17,483,813	126,756	252,573,836	2,490,628
1895 100,256,774	1,644,835	28,760,028	167,267	300,599,257	2,997,169

The figures for bicarbonate of soda are not obtainable in suitable form. The quantity of soda ash (ammonia process) made at Syracuse, N.Y., since 1885, is approximately as follows:—

	Tons.		Tons.
1884, about	11,800	1890, about	67,000
1885 "	15,000	1891 "	72,500
1886 "	31,200	1892 "	81,100
1887 "	35,000	1893 "	98,000
1888 "	50,500	1894 "	105,000
1889 "	52,370	1895 "	107,000

The above represent the total soda capacity of the works. Part of the soda made is transformed into caustic soda (80 tons daily) and into bicarbonate (20 tons daily). Ammonia soda is also made by the Michigan Alkali Co., at Wyandotte, Mich., and by the Mathieson Alkali Co., at Saltville, Va.

The location for an ammonia soda works is a matter requiring careful consideration. The salt and limestone should be near at hand, on the land belonging to the works, if possible; suitable waste places should be near by to receive the lime waste, and there should be available an abundant supply of water of a low temperature for cooling purposes. To be within a reasonable distance of cities using coal-gas is also desirable, so that ammonia may be obtained at cheap rates. At the present time (1894) a good location is in the neighbourhood of Cleveland, Ohio, or near Detroit, Michigan. The works of the Michigan Alkali Co. were the first to be located in the Detroit district, the next being the works of Church and Co. at Trenton; these are being followed by the Solvay Process Co. of Syracuse, N.Y., who propose to place near Detroit a branch works.

There is an abundance of salt, limestone, and cooling water, and also room for the disposal of the lime waste, at the above places in Michigan.

In the Detroit district salt is reached at about 1,400 ft., at Cleveland it is considerably lower, about 2,200 ft. The following (from the Geological Survey of Ohio, "Economic Geology," Vols. V. and VI.) gives the record of a well drilled just outside of the city of Cleveland. The well-head is about 780 feet above tide:—

	Total Depth.	
	Ft.	Ft.
Drift, sand, clay, and gravel.....	40	40
Shale, changing colour.....	1,310	1,350
Limestone, solid.....	310	1,660
Sand, with first salt water vein.....	40	1,700
Limestone.....	290	1,990
Rock salt and shale.....	164	2,154
Shale.....	15	2,169
Limestone.....	81	2,250
Rock salt.....	50	2,300
Shale, bluish.....	40	2,340
Sand.....	10	2,350
Shale.....	18	2,368
Limestone.....	22	2,400
Rock salt.....	20	2,420
Shale.....	10	2,430
Limestone.....	40	2,470
Rock salt.....	5	2,475
Shale.....	8	2,483
Limestone.....	167	2,650
Oil sand.....	8	2,658
Limestone.....	22	2,680
Oil sand.....	6	2,686
Limestone.....	64	2,750

The 40 ft. of sand, unlike most of such entries in the drillers' record in Western Ohio, is the genuine article. The rock salt, 164 ft. in thickness, extending from 1,990 to 2,154 ft., is not a clear uninterrupted deposit, but is broken by both shales and limestone. An analysis of this seam gave the following (N. W. Lord, Chemist, Geol. Survey):—

	Per Cent.
Salt.....	71.24
Sulphuric acid.....	1.80
Lime.....	2.75
Magnesia.....	0.12
Insoluble residue.....	17.92

The bed of "shale," 15 ft., reported by the driller immediately below the rock salt, proves, on examination, to be anhydrite or sulphate of lime. The 40 ft. of bluish shale, reported from 2,300 to 2,340, is also anhydrite. The 50 ft. of rock salt directly overlying it has the following constitution (N. W. Lord):—

	Per Cent.
Salt.....	83.00
Sulphuric acid.....	0.10
Lime.....	1.68
Magnesia.....	0.15
Insoluble residue.....	13.03

The limestone, 167 ft., that extends from 2,483 to 2,650 ft., is a nearly pure dolomite.

The United Salt Co., at Cleveland, manufacture a fine grade of salt for dairy and table purposes; their wells are about 2,200 ft. deep. The limestone found in this part of the country tends in general to run into dolomite, but there is no difficulty in getting a limestone suitable for the ammonia-soda process. In the autumn of the year of the World's Fair 1893 the writer of this paper examined a number of places along the lake shore from Cleveland to Detroit, and also in Western New York, where there is also plenty of salt and limestone, for sites suitable for an ammonia-soda works.

The district around Sandusky, in Erie and Ottawa counties, Ohio, including the small peninsula named Marblehead, jutting out into Lake Erie, and a group of small islands, of which Kelley's Island is the largest on the United States side, constitutes the most important lime-producing region in Ohio. The carbonate of lime ranges from 70 per cent. to 94 per cent., the magnesia from 8 per cent. to 27 per cent., and the insoluble matters from 1 per cent. to 5 per cent. This district is about 50 miles by water west of Cleveland. Kelley's Island furnishes limestone for fluxing purposes. The average composition of limestone received by Cleveland furnaces is given as—

	Per Cent.
Carbonate of lime.....	86.10
Carbonate of magnesia.....	11.49

Prof. Lord gives the following in vol. VI., "Economic Geology of Ohio":—

KELLEY'S ISLAND QUARRIES.

	Ft.
1. Extra cap.....	4
2. Cap rock.....	9
3. Building stone courses.....	6
4. Bottom rock.....	9

Flint underlyine.

	1.	2.	3.	4.
Carbonate of lime.....	97.28	87.10	89.16	77.22
Carbonate of magnesia..	2.00	10.96	9.48	20.19
Alumina and iron oxide..	0.27	0.15	0.20	0.14
Silicious matters.....	0.85	1.49	1.05	1.65

The writer of this paper collected, three years ago several samples of stone from Marblehead. An average sample of the lot contained—

	Per Cent.
Calcium carbonate.....	82.8
Magnesium carbonate.....	12.5

There are several kilns working at Marblehead; one lime works there had 16 kilns using crude oil as fuel; this was in the autumn of 1893. In the early spring of 1895 crude oil rose to a price nearly three times what it was in 1893 and 1894. The western part of New York State is underlain with a fine bed of salt; there is also limestone here of good quality, particularly in the neighbourhood of Leroy, where lime is manufactured. There are a few places in this locality very suitable for the ammonia-soda industry; this part of the State is also intersected by several important railroads. Most of the salt manufacturing towns of Western New York are in the district drained by the Genesee River, and are mainly in the counties of Livingston, Wyoming, and Genesee. New York State produced in 1895, 6,795,000 barrels of salt, 280 lb. to the barrel. There are rock salt mines at Retsof and Livonia in Livingston county, and at Leroy in Genesee county. At Livonia the mine is about 1,100 ft. deep, and the salt 55 ft. thick. The Retsof mine is about 1,140 ft. deep. The brine wells range from about 650 ft. at Leroy in the north, in Genesee county, to 2,400 ft. at Castile, in Wyoming county south. The rock salt has a slightly greyish appearance, due to particles of carbonaceous matter. East of this district, at Watkins, in Schuyler county, and at Ithaca, in Tompkins county, salt has been discovered at 2,250 ft., and it is

claimed that the bed of salt is over 200 ft. thick. A salt works was erected on the lake shore near Watkins, in Schuyler county, in 1894.

The limestone around Leroy and a few other places in this district runs up to 98 per cent. of calcium carbonate. In the summer of 1892 the writer took a number of samples from a quarry near Leroy. An average of these gave—

	Per Cent.
Silicious and insoluble matters.....	3.72
Iron oxide and alumina.....	0.14
Magnesium carbonate.....	3.00
Calcium carbonate.....	92.55

A sample from a large stone being put into a building gave—

	Per Cent.
Silicious and insoluble matters.....	3.45
Iron oxide and alumina.....	0.70
Magnesium carbonate.....	1.86
Calcium carbonate.....	94.20

Two samples of stone from the shaft of the Lehigh Rock Salt Mining Co., about four miles south of Leroy, gave—

	Near Top of Shaft.	Half-way Down.
	Per Cent.	Per Cent.
Silicious and insoluble matters.....	3.05	26.40
Iron oxide and alumina.....	0.25	6.00
Magnesium carbonate.....	0.84	25.20
Calcium carbonate.....	95.82	42.30

At the town of Avon, in Livingston county, there is a bridge over the Genesee River; the pillars supporting the bridge are built of blocks of limestone quarried near Leroy. From the face of one of the pillars the writer chipped off about 40 pieces; an average of these gave—

	Per Cent.
Silicious and insoluble matters.....	3.85
Iron oxide and alumina.....	1.06
Manganese carbonate.....	5.72
Calcium carbonate.....	89.20

The limestone quarried in this district is, as a rule, specular, crystalline and greyish in colour. The presence of a large quantity of magnesia is readily detected, for the specular character is replaced by a dull, close, and very fine grain, and the colour is of a creamy-white shade.

The works of the largest manufacturers of soda by the ammonia process in the United States are at Syracuse, N.Y. They are situated on the south-west side of Onondaga Lake, into which the lime waste liquors from the works run. Complaints are often made about the waste lime running into the lake.

A long stretch of the lake shore is covered with the white mud. The limestone is brought to the works on a cable road from quarries belonging to the company, about three miles west of the works. Rock-salt has not been found at Syracuse; the weak brine obtained there is supposed to result from water which has percolated through saline strata south of the city. As coming from the wells at Syracuse, it contains about 18 per cent. of salt. The ammonia-soda works there were commenced in the early part of 1884, and from then up to 1889 this weak brine was used, being brought to saturation by the addition of bought salt, made by evaporating similar weak brine. During that time soda products brought higher prices than now. Then the crude bicarbonate of soda, as dug out of the filters, simply dried in a current of hot CO₂, and then ground and packed in kegs and barrels, was sold for the price of refined bicarbonate and brought between 40 and 50 dols. per ton. Since 1889 these works have had saturated, or nearly saturated, brine brought by pipe-line from a point about 20 miles south of Syracuse, where rock-salt was discovered at about 1,200 feet. This district is considerably higher above the sea level than is Syracuse. At the wells it is about 400 feet higher, and a small lake situated 3 miles

from the wells is 400 feet higher still. Advantage is taken of these differences of elevation to force the water, first down to the salt and then to the city of Syracuse, thus avoiding pumping expenses. Along the Ohio River, at places in Ohio, West Virginia, Illinois, and Kentucky, a weak brine (about 8 per cent.) is found in boring for gas and oil. An attempt has been made to start a small ammonia-soda works at Brandenburg, Ky., on the Ohio River, about 30 miles west of Louisville. The weak brine is concentrated by burning the gas obtained from the well furnishing the brine; the concentrated brine is then used in the soda works. The output of this small works at the time of a visit of the writer (in January 1895) was about 5 tons per day; the total soda output at Syracuse, N.Y., at that time was equal to 320 tons of soda ash per day, part of this, as already mentioned, being converted to caustic and to bicarbonate; the Wyandotte, Mich., works were then producing about 30 tons. The Mathieson Alkali Co. have works at Saltville, Va.; this place has good natural resources in raw materials, but it lies somewhat away from the points of consumption.

The works of the Solvay Process Co. in the United States, those of Brunner, Mond, and Co. in England, and those of Solvay and Co. on the continent of Europe are the ones producing the largest quantity of soda by the ammonia process, and are to a certain extent allied with each other; but the plant or apparatus for any particular operation is not always the same in each of the works of these companies.

Outside of the essentially chemical part of the apparatus come boilers. In the United States high-pressure water-tube boilers are extensively used.

In England, Lancashire boilers of the Galloway type are mainly used. One of these boilers in an ammonia-soda works there takes about 6½ long tons of slack per day, evaporating about 53 cb. m. of water. Liquor pumps for milk of lime, vat liquor, filter liquor, brine, &c.; these are all of the plunger type, with outside packing. In some works the liquor pumps are actuated by belt, all the pumps being worked from a special shaft and power engine placed for this purpose alone; in others, each pump has its own steam cylinder, and is worked independently. There are also vacuum pumps for filters and maintenance of vacuum on the distiller-absorber-vat system. Power engines, high speed, for running the calciners and mills. Gas producers to supply gas for a densifying furnace.

The limekilns are standing in line. Each kiln is set on four standards, so that a hand wagon can run on a track underneath; the wagon or ear is filled by turning or shaking the grate-bars; the burnt and cooled lime then falls into the wagon. The limestone is burnt with coke as fuel. The gas is taken from each kiln at a point 4 ft. from the top; the gas pipe from each kiln leads down to a common collector pipe running alongside the row of kilns and taking the gas to a washer, through which it passes before going to the compressor. The gas-washer is in some works a vessel built up of cast-iron rings. Between each ring and the one above it is fixed a plate having a central tunnel covered with a hood, filled with small holes to break up the gas into many small streams. A shallow bed of water rests on each plate, and is of a depth sufficient to just cover the small holes of the hood. (See Lunge "Sulphuric Acid and Alkali," Vol. III. (Second Edition), pp. 12 and 46.)

Each compartment of the washer has an overflow pipe which connects it with the next compartment below, so that a stream of water can enter at the top and flow through each compartment to the bottom. In place of this washer, some English works use a coke-scrubber. The gas, after being washed, passes on to the compressor, but on its way there it is mixed with richer gas coming from the calcination of the bicarbonate of soda.

The milk of lime is made in wrought-iron tanks, called dissolvers, having a coned bottom. Above the cone is a sloping grate on which the lime rests. A stirrer revolves below the grate to circulate the water among the pieces of lime. The shaft of the stirrer passes up through the grate, and is turned by suitable gear fixed above the tank. After the milk of lime has been run out, the unburnt stone on the grate is removed by opening a door placed

on the side of the tank at the bottom of the slope. The coned bottom of the tank collects the gritty matters and small pieces of unburnt stone which have fallen through the grate: these are taken out by removing a sliding cover at the bottom of the cone.

The milk of lime, on leaving the dissolver, goes through a sieve, and is then pumped to a large reservoir tank in the main building.

The compressors maintain a suction on both the kilns and on the bicarbonate calciners: the resistance to the passage of the gas through the washers should be as small as possible. Several types of the blowing engine or compressor have been used and are now being used in the ammonia-soda industry. In the matter of valves the simple thick rubber flap valve was early used and is in use still; the poppet valve Ingersoll Sergeant New York compressor has been used; the slide valve of the Bueckhardt (Switzerland) type is in use on the continent of Europe, in England, and in the United States, and very recently the Riedler gas compressor has been adopted. In England the rubber flap valve and the Bueckhardt slide valve compressors are working in the same factory, and in the United States the slide valve and the Riedler compressors are at work in the same factory.

The compressor pumps the gas against a pressure equal to about 54 ins. of mercury, consequently the compressed gas is very hot, notwithstanding the water-jacket on the gas cylinder. This pressure is about 27 lb. per square inch and the theoretical temperature at this pressure (the initial temperature being 60° F.) is several degrees above the boiling point of water, but the water-jacket on the cylinder, and further cooling in gas traps bring down the temperature of the gas entering the precipitating tower to about 30° C.

The ammonia brine as it is first made contains only 38—40 grms. of CO_2 per litre; to raise it to the 70 grms. test it is treated with gas in a separate tower before it is submitted to the precipitating operation; for this work two other compressors are required, and in addition it is necessary to have an extra compressor, standing clean and ready to start at once should any of the others break down. In place of the above compressors three single Riedler compressors, 30 ins. by 36 ins. gas cylinders, may be used, or one duplex and one single.

We have thus far considered the carbonic acid gas, its generation in the kiln, and the engine for handling it; we will now consider the liquor (brine) and note the treatment it undergoes in its passage through the works. A good brine, suitable for use in the ammonia-soda process, should contain about 300 grms. of NaCl per litre, and as little as possible of lime and magnesia. Of these, the magnesia is the more troublesome. The following may be regarded as a good and suitable brine:—

NaCl	298.00 grms. per litre.
CaSO_4	4.00 " "
CaCl_2	1.00 " "
MgCl_2	0.50 " "

In Cheshire, where most of the English ammonia-soda works are located, the brine contains, on the average, more magnesium chloride and less calcium chloride than the brines of Central and Western New York. They compare approximately as follows:—

	Grms. per Litre.	
	Cheshire.	New York.
NaCl	295.00	298.00
CaSO_4	5.00	4.10
CaCl_2	0.93	2.35
MgCl_2	2.60	0.65

Many brines contain also small quantities of iron and calcium bicarbonate. Some brines obtained in Michigan contain sulphuretted hydrogen. The lime salts can be readily precipitated by ammonium carbonate, which is formed or introduced into the brine during the treatment it undergoes in the works; ammonium chloride is also formed in the brine at certain stages. This prevents the magnesia from being completely precipitated, whereas it does not

affect the precipitation of the lime. This unprecipitated magnesia separates out later, when the vat liquor is being cooled, and is apt to fill up the tubes of the cooler.

The fresh brine, on entering the works, goes into a vessel termed a tower washer—so called because in it are washed the unabsorbed gases from the towers. (See Lunge, "Sulphuric Acid and Alkali," Vol. III. (Second Edition), p. 33.) There are two tower washers, one working and the other standing clean, ready to be put into run if anything should happen to stop the first. The tower washer is built up of five cast-iron rings or cylinders. Between each pair of rings is a plate having one large central hole covered by a second plate or hood having many small holes, and having also many teeth or projections around the rim. The small holes and teeth serve to break up the gas into small bubbles as it rises through the liquor. The tower washer has thus five compartments, which are connected with each other by outside overflow

pipes. The brine travels down from one compartment to the next below, and as the outlet of each compartment is about 15 inches above the bottom plate, there is in each a layer of brine of about this depth resting on each lower plate. Each compartment has a nozzle placed level with the lower plate, so that when desired the liquor can be run out. The idea seen in all the apparatus for treating liquids with gases or gases with liquids in the ammonia-soda process is to arrange the liquid in several superimposed layers and to cause the gas to bubble through one layer before going to the next; in this way the richest or strongest gas meets first the liquid richest or strongest in what has to be taken from the gas passing through it. The fresh unused liquid is thus kept at the top of the vessel, to wash out or absorb what has escaped the lower layers, owing to these being more or less saturated with the substance it is desired to wash out or absorb. This idea or principle is what forms the distinguishing feature of the old Coffey's still, and the apparatus of Adam, for distilling alcoholic liquors.

In the tower washer the lime is more or less precipitated from the brine by the ammonia and ammonium carbonate carried in by the unabsorbed gases from the towers, but the precipitate remains in the liquor, and goes with it until it reaches the vats, where the precipitate is settled out. The waste tower-gas, after passing through the tower washer, goes into the atmosphere. The liquor leaving the bottom of the tower washer now goes to the absorber.

The absorber is a vessel of cast-iron rings formed into compartments like the tower washer. (See Fig. 1.) The gases drawn off by the vacuum pump are sent to a small scrubber, down which runs the raw brine just coming to the works, or, in place of this, to a small washer supplied with water, which, when strong enough, is sent along with other liquor to a distiller. The compartments of the absorber are provided with large manholes, and the overflow pipes have swinging covers to facilitate cleaning.

Fig. 2.

The fresh brine enters at the top to act as a scrubbing liquid. The curves of the plates and hoods in the absorber are reproductions of those in the distiller—a vessel to be described later.

The ammoniated brine, is run out continuously from near the bottom, going to a series of three or more vats, where it is settled and stored. The settling is necessary in order to get rid of the precipitated lime and magnesia of the brine, and thus prevent these from getting into the soda ash. If unsettled liquor is sent to the tower where the bicarbonate of soda is formed, the sediment is collected along with the bicarbonate, and on calcining the latter we get an ash containing lime and traces of iron, this last giving to the ash a yellowish tint. A small quantity of ammonium sulphide helps to prevent the liquor from taking up iron from the sides of the vessels and pipes.

The vats are built up of four cast-iron rings. Each vat rests on four iron pipe pillars taking hold of the vat at the top of the cone. Each of the four rings forming the body of the vat is provided with nozzles for pipe connections; and I may say here that all the vessels and apparatus used in the ammonia-soda process should be well provided with facilities for making connections with each other. Another point that is apt to be overlooked is that a gas or vapour is a material substance, and therefore requires room or space for its existence. The increased production of ammonia-process soda in Europe, England, and the United States during the last few years has been largely attained by a recognition of the above, the openings and passages in the several apparatus having been made larger, the apparatus otherwise being of about the same dimensions as before, thus enabling larger volumes of gas and liquor to pass through in a given time. The mud of carbonates of lime and magnesia settled in the cones of the vats is drawn out in charges every two or three hours, and treated to obtain the ammonia. In a large works in England the mud is sent to the distiller, whereas in a works at Syracuse, N.Y., the mud was drawn into a closed tank provided with a stirrer, raw brine was then run in, and the whole well mixed. After settling again, the clear liquor was run out to go to the absorber, and the operation repeated until the mud was free from ammonia. The method by distillation, however, is more direct, and altogether the handiest way of dealing with it. The absorber vats and distiller are the vessels included in a vacuum circuit, the object being to facilitate the working of the distiller. The atmosphere above the liquor in the vats is of course saturated with ammonia, and in the emptying and filling of the vats is alternately drawn in and driven out, but the tops of the vats being connected with the absorber, this ammonia is all retained. In place of this absorber two separate vessels have been used; these were simple wrought-iron tanks, having no internal hoods nor plates, the liquor in each being one undivided mass. One tank was called the absorber and the other the vat washer; they were placed so that liquor from the tower washer could flow naturally into the vat washer, and from this to the absorber, and from here to the vats. The ammonia gas from the distiller passed down a pipe to the bottom of the absorber, bubbled up through the mass of liquor, then up through the vat washer, and then passed into the tower washer. It will be seen that the present absorber is a combination of the old vat washer and old absorber, but whereas these were simple tanks, the present absorber has a number of compartments. Mr. H. Schreih has described an absorber similar to this some years ago. See the *Chemiker Zeitung*, 1890, page 490.

We now come to the tower where the settled vat liquor is treated with carbonic acid gas. The tower and the distiller constitute a sort of dual backbone around which the other apparatus clings. The tower is built up of cast-iron rings and plates. The tower plates are composite or double plates, that is, each bottom plate and its cover or perforated plate form one casting. The cooling of the liquor in the tower has for a long time been effected by trickling water down the outside of the tower; but some works use cooling pipes and tubes running into and through the tower, seeking to cool the tower liquor by a more efficient way than by outside cooling (see the *Chemical News*, Oct. 25th, 1878, and this *Journal*, 1882, p. 110).

of lime and iron, but when the total matters insoluble in water are over 0.5 per cent. of the soda ash, we know that the vat-liquor was not settled well enough. Other devices have been and are being tried to provide continuous and more or less automatic filtering. Some 16 years ago there was in a salt works at Northwich, England, a small experimental plant for making salt. The apparatus consisted essentially of an iron cylinder closed at the ends, having hollow trunnions and heated by steam inside. The cylinder revolved in a tank of brine, so that the lower part dipped in the brine, and thus accumulated a layer of salt on the outside, and a fixed scraper, against which the cylinder came, took off the salt. The idea running through the above has been embodied in a filter which is being tried in several ammonia-soda works. A cylinder closed

at both ends, having its shell formed as a grid or grating covered with filter cloth, forms the filter bed; it revolved in a tank containing tower liquor, dipping into the liquor at its lower part. A vacuum is maintained inside the cylinder by a connection through the axis, and a suction pipe dipping down to near the bottom takes away the clear filtered liquor. In this way a thin layer of bicarbonate is taken up on the outside of the cylinder, is washed and dried, and taken off as in the experimental salt plant. Centrifugal machines have also of late years been again brought into use. These will turn out bicarbonate containing only 10 per cent. and less of moisture, against 24 per cent. to 25 per cent. from the filters; but against the drier bicarbonate got from their use we have a greater expense in keeping them in running order and a rather large labour account.

The filter liquor reservoirs, where the clear liquor and washings from the filters are collected, are either large cisterns built of stone and brick in the ground, or ordinary iron tanks resting on the ground floor. The former method is in use in the United States and the latter in England. In these reservoirs are put other strong ammonia liquors, such as concentrated gas water, testing about 16 per cent. of NH_3 . This strong ammonia liquor is bought to supply the working loss of ammonia, and is stored in separate special tanks, a certain quantity being drawn therefrom and put into the filter liquor reservoirs as required. The working loss of ammonia runs from $\frac{1}{2}$ per cent. to 2 per cent. of ammonium sulphate on the soda ash made. The underground reservoirs, built of stone or brick, are lined inside with Portland cement, and covered with brick arches resting on I beams. There are other such cisterns for holding other ammonia liquors. The filter liquor reservoirs above ground are ordinary wrought-iron covered tanks holding about 40 M.

All liquor coming from the filter liquor reservoirs is called filter liquor, no matter where it originally came from. For good distillation, this liquor ought to be kept regular in test.

We now come to the distiller, in which the filter liquor is treated, to obtain again, in an active form, the ammonia which has enabled us to convert common salt into bicarbonate of soda, and has itself become ammonium chloride. Filter liquor contains, beside ammonium chloride, the excess of ammonium carbonates, the filter washings, more or less concentrated ammonia gas water, a small quantity of ammonium sulphate, and all the common salt which has not been converted into soda. In some works it also contains a strong liquor resulting from cooling the ammonia gas coming from the distiller. About 18 years ago stills were used in the ammonia-soda process to work up the filter liquor. A charge of liquor was run into a still, then a charge of lime, and when the ammonia was boiled off, the waste liquor was run out and another charge treated in the same way. They were used in sets of four, three working and one empty, the steam and ammonia of one passing through the other two and then up a heater-tower to heat the incoming liquor; but now, with the distiller, the operation goes on continuously, filter liquor and milk of lime going in, ammonia gas coming from the top, and waste liquor from the bottom. The distiller is a tall vessel; the lower half is built up of wrought-iron plates, divided into 12 compartments by means of horizontal cast-iron plates, each having a large central hole or tunnel covered by a hood of umbrella shape; the upper half is built up of cast-iron rings, also divided into compartments by cast-iron plates, which act as dash-plates to break up the liquor in its descent. The upper half is called the heater; its function is to heat the filter liquor, and so drive off the ammonium carbonates before it reaches the lower half, where it meets the milk of lime, which is pumped into the top wrought-iron compartment. On meeting the milk of lime, the fixed ammonia salts are decomposed and the ammonia set free. During the course of the liquor down the remaining compartments the ammonia is driven out by steam forced in at the bottom compartment. The ammonia gas coming from the top of the distiller has a temperature of about 80° to 85° C. This is too hot to allow it to go to the absorber direct; moreover, it contains a quantity of steam which would dilute the brine. It is therefore first passed through a condenser, where it is cooled. This

strong liquor in some works goes down to the filter liquor reservoirs. In some works this condensate is run back into the heater at a point about half-way down the heater.

Fig. 4.

COOLER OR CONDENSER.

The distiller condenser is a vessel built up of cast-iron rings; through these are placed about 150 tubes; a water chamber is fitted at the top and bottom. The cooling water enters at the bottom, rises up through the tubes, and flows away at the top. The distiller will run from 30 to 70 days, depending on the quality of the lime used. The heater part is seldom cleaned, as no lime goes into it except what may splash into it from the upper wrought-iron compartment, and there is very little deposit from the filter liquor itself; but the lower half is cleaned about as often as stated.

The scale formed in the lower half is sometimes 3 ins. thick; in the upper wrought-iron compartments the scale is soft and contains much calcium carbonate, while in the lower ones it is hard and is mostly calcium sulphate; this sulphuric acid comes from the calcium sulphate originally in the brine. The distiller is cleaned by chipping off the scale; one or, where required, two men go into each compartment and take off the scale with chipping hammers. The scale in a distiller has been softened and more or less removed by boiling or distilling in it ammonia liquors without using lime. From one or more of a number of possible causes, it sometimes happens that the liquor arriving at the bottom of the distiller is not "sweet," that is, not free from ammonia. If this arises from a deficiency of lime, a quantity of milk of lime is allowed to go into the bottom compartment (this compartment has a branch from the lime pipe), the exit liquor pipe from the distiller is closed, and an attempt is made to work off the ammonia before this compartment, which is purposely made larger than the others, can fill up. If this cannot be done, and the quantity of ammonia present is small, it is better to let it go than to deal further with it; but if the liquor is strong, and the trouble is only a strong spot, as it were, in the line of liquor travelling down the distiller, the liquor can be run from the lower compartment into a spare tank and worked up afterwards. Of course, a distiller will get strong, even with plenty of lime present, if the supply of steam becomes lessened. Anything more than a temporary irregularity has to be dealt with according to the trouble existing.

Beside the distillation of filter liquor as just described there is a miscellaneous liquor called "weak liquor." This is mainly composed of the liquor got by condensing, scrubbing, or washing the gas coming from the calcination of the bicarbonate, and the leakages and drippings from strong liquor tanks. This liquor is worked up without lime

in a small special distiller. The condensate from the bicarbonate calcination contains a little soda, and this decomposes any fixed ammonia salts which may get into the liquor. The weak liquor distiller will work up also the weak ammonia water from gasworks, containing about 2 to 3 per cent. of ammonia. The ammonia-gas from the weak liquor distiller is either made to follow the same path as the ammonia from the large distiller, or it is condensed to a strong liquor, and this run into the filter liquor reservoirs, so that it ultimately goes into the absorber, whichever way is adopted.

The liquor and lime going to a distiller are so adjusted that the exit liquor shall have a small excess of lime. The waste liquor is a solution of calcium chloride and sodium chloride mainly; it contains also the excess of caustic lime, calcium carbonate (representing both unburnt stone and any CO_2 not driven off in the heater), calcium sulphate (representing that contained in the lime and the sulphate in the brine), and the miscellaneous impurities of the limestone.

The waste liquor varies considerably in composition even in the same works, and necessarily does so in liquors from works in different localities using different qualities of limestone.

Efforts are made in some works to settle the waste liquor and return the lime mud to be mixed with fresh milk of lime going to the distillers; particularly is this the case in England, where the limestone used (Buxton) contains less impurities than the limestone of Central New York. Where the lime mud is used over again, a milk of lime testing about 280 grms. CaO per litre is reduced by the admixture to about 180. The waste liquor is run on to waste land, and if objections are raised against it finding its own way to rivers or watercourses, large shallow ponds are made by making banks with the settled mud to inclose the liquor, the ponds being made of such a size that the liquor run in at one end will run out at the other end nearly clear or free from sediment.

We have now followed the brine along all its course through the works.

Stock of Ammonia.—This is expressed in kilos. of ammonium sulphate. Per ton of ash made per day there should be provided ammonia equal to 2,000 kilos. of ammonium sulphate; of this about 1,250 kilos. are in use in the working liquors, while 750 are in the form of reserve liquor, consisting usually of ammonia water from gasworks concentrated until it contains about 16 per cent. of NH_3 .

We will now return to the washed bicarbonate left in the filters. It is dug out with shovels and sent to the calciners. The apparatus for drying and calcining the damp bicarbonate into finished ash is not the same even in affiliated works. The largest ammonia-soda works in the United States follows the lead of the Solvay ammonia-soda works on the continent of Europe, whereas the largest of the English works, although affiliated with these, uses different apparatus, conducts its own experimental work in regard thereto, and generally carries on the manufacture after its own methods. The old Solvay calciner (see U.S. Pat. No. 136,463, March 4, 1873), shaped like a saucer, is in use in the United States; it is being replaced as circumstances permit by the calciner described in U.S. Pat. No. 386,664, July 24, 1888. This last, however, as used is a cast-iron cylinder about 60 ft. long by about 5 ft. in diameter; it is supported at the ends and at the middle on roller bearings, and revolved by gear fixed at the middle. A furnace chamber is built around each half of the calciner, the two chambers being connected by underground flues. The middle roller bearings and gear are thus situated between the two furnace chambers; the fire gases pass through the whole length, heating the shell of the calciner on the outside. Producer gas is used as fuel. Provision is made in the bearings of the calciner at one end for the expansion or extension of the shell by the heat. A heavy chain lying along the length of the cylinder propels the ash forward as the calciner revolves. The old Solvay calciner has not been used in England for many years; there the Thelen machine calciner is mainly used. A description of the original Thelen dryer can be found in German in *Die Chemische Industrie*, 1878, page 7. For drying

ammonia-process bicarbonate it is built of cast-iron half-cylinders, bolted together; a shaft having a number of arms fixed along its length, fitted with propelling blades, is fixed longitudinally through the pan and given a rocking motion of a quarter of a revolution by a worm and wheel. The pan rests on brick walls and is heated underneath by gas or coal fires. Both in the new Solvay calciner and in the Thelen machine the bicarbonate is fed in at the fire end and is received at the back end into a conveyor, from which it is taken by an elevator to a cooling conveyor placed near the roof. This cooling conveyor is a revolving shell, having an inside screw fastened on the shell; this method avoids having a shaft turning in the hot ash and so avoids dust; it also has greater cooling surface than the ordinary conveyor. When cooled, it goes to the milling and packing plant. Only a small proportion of the ash from these calciners need go through the mill, because it is not so lumpy as heavy fired, that is direct fired ash. By referring to the analysis of the bicarbonate it will be seen that there is considerable water and ammonia, and also, of course, carbonic acid gas, coming from the operation of drying and calcining this. These gases leave the calciners at a point near the charging hole at the fire end, and are either passed at once through a condenser (similar to the distiller gas condenser) standing near the calciner, each calciner having a condenser; or a number of calciners have their gas pipes arranged to lead into a common trunk pipe, which carries all the gases and vapours to a series of three or four condensers. In the condensers the steam and most of the ammonia are removed. The gas, CO_2 , with a little ammonia, pass through a washer similar to the kiln gas washer, or, in place of this, up a coke tower, in which the remaining ammonia is taken out. The carbonic acid gas then passes to the kiln gas pipe, where, the two, mixing go to the compressor as has been described. The condensed steam and the water of the washer go to the weak-liquor distiller. The gas contains about 60 to 80 per cent. CO_2 , depending on the care exercised in preventing air being drawn into the calciner. Soda ash, made in vessels heated on the outside, as in the above calciners, is light-weight ash. This ash, if packed and shaken into a glass jar holding 1,000 c.c., will have a weight of 900 to 1,000 grms. for this volume, whereas this ash, when subjected to fire playing direct upon it until near the point of fusion, cooled, and ground to the same condition as the other, will weigh 1,350 grms. for 1,000 c.c. For densifying ash a Maetear or similar furnace is employed.

When densified ash is wanted the calcination in the Thelen or other calciner need not be pushed so far as to fully convert the NaHCO_3 into Na_2CO_3 , because this will be completed by the further heating in the Maetear.

Soda ash made in England for the American trade is almost entirely dense ash, and is packed in casks holding about 15 long cwt. Soda ash made in the United States is mostly light ash, and is packed in barrels holding about one-fifth of the above; it is also packed and sold in bags. All the above refers to full-test 58 per cent. ash; when 48 per cent. is wanted either common salt or salt cake, or both, is added in sufficient quantity to reduce the test. Caustic ash is made by adding strong caustic liquor to ordinary 58 per cent. ash, or to 48 per cent. ash and calcining again. These 48 per cent. and caustic ashes are really imitation Leblanc ashes. The following figures show the chief constituents of full-test, 58 per cent., and the two kinds of 48 per cent. :—

	58 per Cent.	48 per Cent.	48 per Cent.
Na_2CO_3	98.00	81.10	81.10
NaCl	1.20	17.60	12.86
Na_2SO_4	0.12	0.20	5.12
Impurities	0.10	0.12	0.75

The impurities are chiefly calcium carbonate, magnesium carbonate, and iron oxide. These are kept out of the 58 per cent. by good setting of vat liquor; the larger quantity in the 48 per cent. ash arises from the impure salt and salt-cake.

The market price of soda ash in the United States and in the United Kingdom is based on a supposition that the ash quoted is 48 per cent. This is a relief of the trade in the old Leblanc days. When New York or Boston papers quote ammonia alkali 58 per cent., 95 c. and 1.00 dol., this means (taking, for example, the first mentioned price) that the real price is $\frac{95 \text{ c.} \times 58}{48}$ per 100 lb., that is, 1.14 dols. for 100 lb. of 58 per cent.

The United States stands at the front in the manufacture of iron and of mechanical appliances, and holds an eminent position in textile industries, but in the alkali trade there is ample room for growth, which ought to be stimulated by the possession of first-class raw materials, and a home market calling every year for large imports.

OPENING OF THE DAVY-FARADAY LABORATORY.

WE are indebted to the *Pharmaceutical Journal* for the following account of the formal opening of the new Davy-Faraday Laboratory of the Royal Institution, by H.R.H. the Prince of Wales, which took place in the lecture theatre of the Royal Institution on Tuesday afternoon, Dec. 22.

Dr. Ludwig Mond commenced the proceedings by reminding the Chairman that under the auspices of his august father, whose enlightened mind had fully realised that the pursuit of pure science is the most potent factor in the promotion of the intellectual and material progress of nations or of humanity at large, a movement was set on foot fifty years ago to found an institute in connection with the Royal Institution for the pursuit of pure chemistry. It was intended that the proposed institute should not only give practical and systematic instruction to students, but also provide a place where research work could be conducted by fully qualified investigators. This project was approved by Faraday and Brande, the then professors, but the idea had to be abandoned because sufficient accommodation could not be found within the precincts of the Royal Institution. The first part of the scheme, however, was carried out a few years later by the foundation of the Royal College of Chemistry. The second part, that of providing a place where original work could be carried on by a number of independent investigators, has been waiting until now for its realisation. On learning these facts the speaker determined to found in London a Research Laboratory in purely scientific chemistry and in physical chemistry, that borderland between chemistry and physics from which in his opinion we may hope to learn more about the real nature of things than from any other branch of natural science. He had also come to the conclusion that such a laboratory would derive the greatest advantage if it could be associated with the Royal Institution of Great Britain, which has during its long existence made the promotion of research in those sciences one of its main objects, and the laboratories of which have been productive and are still productive of such marvellous results at the hands of the eminent professors elected by the Institution. The commodious house immediately adjoining the Royal Institution was therefore acquired, and a scheme submitted to the managers, which they readily accepted with unanimity. Work was immediately commenced to alter the building so as to make it suitable for its new purpose, and, thanks to the advice which has been freely extended by scientific men all over the world, and the active co-operation of Lord Rayleigh and Prof. Dewar, Mr. Flockhart, the architect, and Mr. Robert Mond, to whom has been left the selection of the apparatus and the equipment of the place generally, the laboratory which His Royal Highness was asked to inaugurate would stand favourable comparison with any other laboratory in or out of England as to the completeness and convenience of its appliances. It is provided with the best instruments made at the present day, and is unique of its kind, being the only public laboratory in the world solely devoted to research in pure science. In order to ensure its continued usefulness, the Laboratory has been endowed so as to cover the cost of maintenance of the fabric and all necessary current expenses, and it has been named the Davy-Faraday Research Laboratory, in perpetual

memory of those two great pioneers of science. Lord Rayleigh and Prof. Dewar have consented to undertake the duties of directors of the Laboratory without emolument, and an experienced superintendent has been appointed in the person of Dr. Scott, nothing being now wanting for its success but a number of investigators, competent and ardent, to continue the great work of this century, the unravelling of the secrets of Nature. As soon as His Royal Highness declared the building open, persons of either sex or any nationality would be welcome within its walls if they could satisfy the Laboratory Committee that they were fully qualified to undertake scientific research in pure and physical chemistry, preference being naturally given to those who have already published original work. In establishing the Davy-Faraday Laboratory, the speaker had, at the same time, been able to enlarge the old laboratories of the Royal Institution, and also to make additions to its library and reception rooms, which he hoped would prove a convenience to its members.

The Prince of Wales then replied, saying it afforded him much satisfaction to assist at the opening of the beautifully arranged and well equipped Research Laboratory which this country owes to Dr. Mond's generosity, and he congratulated the members of the Royal Institution of Great Britain upon this most important accession to its resources. The Royal Institution has always enjoyed a world-wide reputation, thanks to the marvellous work of the succession of illustrious men whose researches have very largely contributed to secure and maintain for this country a foremost position in science and its applications. The identification of the Laboratory with the names of two of the most eminent former Professors of the Royal Institution, Sir Humphry Davy and Michael Faraday, was a graceful act on the part of Dr. Mond; and most gratifying evidence of the great faith entertained by Lord Rayleigh and Prof. Dewar of the benefit to the promotion of science which this wisely applied munificence is destined to realise, was afforded by the fact that they have undertaken the important duties of directors of the new Laboratory without any remuneration.

THE "WILLIAM GOSSAGE" LABORATORIES, UNIVERSITY COLLEGE, LIVERPOOL.

On December 12th the new chemical laboratories of the Liverpool University College were opened by the Earl of Derby, when an address was delivered by Prof. W. Ramsay.

The first portions of the chemical laboratories of the College, which were completed in 1886, have for the past three years been insufficient for the increasing number of students and especially for the development of the more advanced work required. A large laboratory for senior students and additions to the research laboratory were especially necessary—a want which has now been fulfilled chiefly by the liberality of Mr. F. H. Gossage and Mr. T. Sutton Timmis. Some time ago these gentlemen undertook to build and fit up a farther section of the building, including the largest of the main laboratories and other rooms, at a cost of 7,000*l.* These laboratories they have presented to the College as a memorial of the late Mr. William Gossage.

Other portions of the buildings have been erected by subscription, amongst the donors being Sir John T. Brunner, M.P., 1,000*l.*; Mr. E. K. Muspratt, 1,000*l.*; and Messrs. Lever Brothers, 1,000*l.* The new buildings complete the Brownlow Street frontage, and include a large laboratory 60 ft. by 32 ft., with benches fitted up for 44 advanced students, an adjacent room provided with a new form of heated sand-bath and other appliances for the service of the main laboratory, and, in the basement, an additional lecture room to seat 70 or 80, a preparation room, and a gas-analysis room. These five rooms, which are lined with ivory-glazed bricks, constitute the "William Gossage" laboratories. The other new buildings are a metallurgical laboratory with furnaces and other equipment, an addition to the research laboratory, a store for apparatus and chemicals, a dynamo room, electric accumulator room, and a heating chamber. In his address Prof. Ramsay contrasted the opportunities of studying chemistry to-day and in Faraday's time, rather regretting that students now have only to go to the apparatus shop round the corner for

what they want. It would be better for them, he said, if they had to rough it a bit, for as an engineer should be able to make his own tools, so should a chemist. Starting from crude material, he should be able to produce pure chemicals; starting with glass tubes, he should be able to extemporise a blow-pipe, and make the most complicated apparatus. He should be a reasonably good gasfitter and turner; he should be able to solder a joint, and he should be able to turn to account nearly every apparently useless article.

Prof. Campbell Browne reviewed the development of the chemical department of the College, and pointed out the suitability of associating the gift with the name of William Gossage, whose career as a chemist and as an inventor he sketched.

The Earl of Derby afterwards spoke; then Mr. Sutton Timmis (on behalf of Mr. F. H. Gossage, who was unfortunately prevented by illness from being present) presented the Earl with a silver casket containing the key of the building. Lord Derby, followed by the rest of the assembly, then proceeded to the laboratory, unlocked the door, and formally took possession of the building on behalf of University College.

OPENING OF NEW LABORATORIES AT PERTH.

On December 24th Sir Robert Pullar opened the new laboratories at Sharp's Institution, Perth, which have cost over 6,000*l.* The extensions, which were designed by Mr. Murray Robertson, of Dundee, comprise new chemical and physical departments, and a re-arranged art department. The chemical laboratory affords bench accommodation for 30 students, and the lecture-room will seat 40. The physical laboratory can accommodate 24 students working at a time. To this a dark room for galvanometric and photometric work is attached. The whole is well furnished with modern apparatus.

I.—PLANT, APPARATUS, AND MACHINERY.

Refrigerating Apparatus (for Liquefying Air and Separating Gaseous Mixtures). C. Linde. The Engineer, 1896, Nov. 13 and Nov. 20, 485—486 and 509.

AFTER a discussion of critical temperatures (containing a useful table and diagram), the author gives an account of previous methods and apparatus for liquefying gases. All

* Any of these specifications may be obtained by post by remitting 8*d.*—the price now fixed for all specifications, postage included—to Sir Henry Reader Luck, Comptroller of the Patent Office, Southampton Buildings, Chancery Lane, London, W.C.

mechanical processes for reducing temperature are based upon the expenditure of "internal" or "external" work. Refrigerating machines are often classified as "evaporative machines" and "cold air machines." In the former it is mainly the equivalent of the internal work—latent heat—that is abstracted; in the latter it is mainly the equivalent of the external work. The action of Linde's machine consists in eliminating heat from the gas to be liquefied, exclusively by expenditure of internal work until reduction below the critical point and condensation have been effected. In the liquefaction of air, its constituents (considering nitrogen and oxygen only) pass simultaneously into the liquid state, although the boiling point of nitrogen is not inconsiderably below that of oxygen. On the other hand, in subsequent evaporation the more volatile nitrogen separates first. A "separator" is described by which more or less pure oxygen is obtained by the liquefaction and evaporation of air.

The first successful experiments with Linde's refrigerator were made in May 1895, using the compressor of a carbonic acid cold-vapour engine as an air compressor. After equilibrium was established, about 3 litres of liquid air were obtained per hour. The liquid was of bluish colour, perfectly clear, and it contained 70 per cent. of oxygen. With a Whitehead compressor and improved apparatus the period of temperature decrease was reduced 15 to 5 hours, whilst in a third series of experiments with a Brotherhood compressor it was reduced to 2 hours. 0.9 litre of liquid air was produced per hour, and was found to contain about 40 per cent. of oxygen.—D. E. J.

PATENTS.

Material for Filtering Water, Sewage Effluents, Saccharine Juices, Alcoholic Liquors, Illuminating Gas, and other Liquids and Fluids, and for Use in the Manufacture of Steel: Impts. in and connected with the Manufacture of. G. MacDonald, London. Eng. Pat. 19,352, Oct. 23, 1895.

A porous magnetic oxide of iron is made by heating iron ore, pyrites, waste from aniline works, &c., in small lumps, and in presence of vapours of cheap hydrocarbon oil, until the material is freely attracted by a magnet. By continuing the reduction beyond this state, a magnetic carbide is formed useful for steel-making as well as for filtering. The inventor calls this "steel oxide."—L. A.

opening E, through which the material, in the form of a syrup, or in a semi-fluid condition, is introduced for the purpose of being dried, and a second opening F, through which hot air is introduced by a fan. The material to be dried is fed on to the outer surface of the cylinders C, to which it adheres, and when dry, falls on to the floor of the chamber A, whence it can be removed by suitable means.

—R. B. P.

Separating [by Filtration] Insoluble Substances from Liquids, Impts. in the Method of and Apparatus for. W. E. Heys, Manchester. From J. Hundhausen, Hamm, Westphalia. Eng. Pat. 22,920, Nov. 30, 1895.

This apparatus consists of a flat tank provided with a perforated false bottom, over which a band of filtering

Air-Pump [Torricellian], An Improved, especially useful for Exhausting or Diminishing the Pressure in Vacuum-Pans, Stills, and other Vessels. J. A. Wanklyn and W. J. Cooper, New Malden, Surrey. Eng. Pat. 20,658, Nov. 1, 1895.

An upright cylinder is provided in its upper portion with, first, a comparatively wide aperture, surmounted by a funnel-shaped reservoir containing water, glycerin, oil, mercury, &c., and having a stopper; and second, with a narrow pipe having two branches, each provided with a good stopcock, one leading to the vacuum-pan or still, the other being an air-vent. Below, the cylinder is provided with an outlet, also having a stopcock. In use, the stopcocks on the outlet and tube leading to the vacuum-pan are closed: the others are open. The cylinder then fills with liquid from the reservoir, the air escaping through the vent. On reversing the valves, the liquid flows away from the cylinder, thereby creating a vacuum, by means of which the still becomes exhausted.—R. S.

Preparing Solutions of Definite Strengths, Apparatus for. R. P. Roberts, Camberwell, London. Eng. Pat. 22,470, Nov. 25, 1895.

A vessel, as a bottle, has marked thereon a scale or scales graduated, by trial, according to the increased bulk of the liquid due to the added solid, the zero of the scale being a measure of the liquid, and the graduations thereof indicating the levels to which the liquid will rise for each addition of solid, so as to make a solution of any definite strength. The invention is described in connection with making up solutions of hypo. for the use of photographers.—R. S.

Drying Semi-fluid [Syrups, Slurry, &c.] and like Materials: Impts. in the Method of and Apparatus for. W. E. Heys, Manchester. From J. Hundhausen, Hamm, Westphalia. Eng. Pat. 22,918, Nov. 30, 1895.

The apparatus consists of a series of cylinders C, mounted on spindles R, which are carried by a flat-link chain k at each end. Each spindle carries a star wheel S, the teeth of which touch the frame B, and, as the cylinders are carried along by the chains, cause them to rotate. The chains pass over sprocket wheels K K', K being driven by the gearing shown at S, whilst K' is fitted with a tightening gear W. The whole is surrounded by a casing A, with an

cloth or like material travels. The liquid passes through the filtering band and false bottom, being assisted by suction applied underneath, and the insoluble material is deposited on the travelling band. The latter passes over a drum outside the flat tank and discharges the material deposited on it into a transverse trough fitted with an archimedean screw, which in turn transfers the insoluble material into a suitable receptacle, or into a conveyor.—R. B. P.

Drying Sensitive Substances [Starches, &c.]: Impts. in the Method of and Apparatus for. W. E. Heys, Manchester. From J. Hundhausen, Hamm, Westphalia. Eng. Pat. 22,924, Nov. 30, 1895.

The apparatus consists of one or more rotating chambers hexagonal in cross-section. Each chamber consists of

a central tube carrying arms which support longitudinal wooden strips. To these are attached cloth walls forming an inner and outer polygon, between which the material to be dried passes from one end to the other of the chamber. If more than one chamber is used, the material passes successively through each. At the same time a current of air is caused to flow along the chambers, which carries off evaporated moisture, and an internal stirring device may be fitted. One or more of these chambers are surrounded by an outer casing, which also contains suitably placed steam pipes for supplying the necessary heat. Steam may also be passed through the central tubes. Modified constructions are also described.—R. B. P.

Plastic Material from Asbestos, An Improved Process for the Manufacture of a Mouldable Mass or Objects and Articles from Asbestos Fibre or other Fibrous Material or Fibrous Produce. L. Grote, Landsberg-on-the-Lech, Germany. Eng. Pat. 24,163, Dec. 17, 1895.

The fibrous material (asbestos, &c.) is steeped in a hot solution of "soluble glass," glue, and formaldehyde. The material is then immersed in solution of a salt of alumina, baryta, strontia, and finally the parchment-like material is reduced to powder and subsequently worked up with one-third of its weight of soluble glass solution, and one-sixth of its weight of lead oxide (litharge).

Sheets of the material pasted together and subjected to hydraulic pressure become perfectly hard, and may be worked by means of a saw, plane, file, or lathe. The objects, such as vats, buckets, &c., produced by moulding, are said to be acid-proof, waterproof, and fireproof.—V. C.

Separating Substances of Different Sizes or Specific Gravities, Impts. in Apparatus for. W. Johnson and H. Walker, Leeds. Eng. Pat. 16,616, July 27, 1896.

The material to be sized, is fed from a hopper on to a sieve, which retains the largest particles and delivers them into a chute. The material passing through the sieve falls into a closed chamber, in the side of which is an opening leading to a fan, preferably of the Blackman type. As the material falling down from the sieve passes this opening, all the finest particles are sucked away by the fan and deposited in a second chamber.—R. B. P.

Uniform Temperature in Laboratory Ovens, Incubators, Drying Rooms, and the like, An Improved Method of and Apparatus for maintaining. W. R. Lake, Southampton Buildings, Middlesex. From A. Schwabe, Berlin, Germany. Eng. Pat. 19,764, Sept. 7, 1896.

The method consists in submitting the chambers to the heating action of a liquid, the temperature of which is maintained constant by causing hot gases to pass around the sides of the chamber, and regulating the admission of these hot gases by a float balanced in the fluid. In the example shown, the chamber to be heated is surrounded by a fluid jacket, and the latter by a space for hot gases from a burner which is capable of raising the temperature higher than required. When the temperature of the fluid rises to the point for which the apparatus is set, the float sinks, and allows a ball or cup, filled with shot or other weights, and connected to it by a chain, to descend more or less upon the burner. Should the temperature fall the float and cup rise.—R. S.

II.—FUEL, GAS, AND LIGHT.

Hard Coal, Upper Silesian. Bremme. Zeits. d. Ver. d. Ing. 1896, 1185.

UPPER SILESIA is richer in coal than any other district of similar size on the Continent, the seams worked ranging from 3 to 7 metres and occasionally 9 to 12 metres in thickness. The coal is very pure, with a low content of ash, and with less than 1 per cent. (average) of sulphur. Most of the coal now won is close-burning long-flame coal, altogether unsuitable for coke-making, and only a little cherry-coal—the nearest approach to bituminous coal—is met with. The bituminous character of the coal decreases from the sole up to the hanging wall, and from west to east of the Zabrze-

Myslowitz deposit. The best coal for coking is that obtained from the extreme west of the field—at the Königin Luise Colliery, lowest seam, and now and again fairly good coal for this purpose is met with in the upper seams where the cover rock is impervious to water and air.

Despite all endeavours to obtain good coke from mixed upper and lower seam coal, the product is not nearly so well suited for smelting work as that obtained from other districts, and it is considered that this defect can only be surmounted by employing the lower coal alone for the manufacture of coke.—C. S.

Coal-Dust, Firing with; and Coal-Grinding Processes. Zarniko and Tropfe. Proc. Inst. Civil Eng. 126, (iv.), 66—64. From Gesundheits-Ingenieur, 1896, 210.

TESTS of the Wegener, Frieleberg, and Schwartzkopf systems of firing with powdered coal were undertaken at the Moabit Infirmary, Berlin, and the last-named apparatus gave an effective value of 80 per cent., with a perfect consumption of smoke. In a sugar manufactory at Algermissen a saving of 22 per cent. of fuel has been effected as compared with the usual combustion on fire-bars, whilst in a cupola at Vienna the saving amounted to 45 per cent.

—W. G. M.

Petroleum Consumption in Germany. J. für Gasbeleuchtung, 39, [47], 775.

THE consumption of petroleum in Germany increases steadily in the face of the competition offered by gas and electricity, 811,058 tons having been imported in 1895, as against 785,192 tons in 1894, and 556,887 (average) in 1886—1890. The increase per head of population in the period between 1891 and 1895 averages 3·21 kilos. per annum over the figures for 1886—1890, viz., 14·82 against 11·61 kilos. The home production is small but growing—1,309 tons in 1880; 5,665 tons, 1885; 11,513 tons, 1890; and 15,620 tons, 1895 (quinquennial averages). The largest share of the import trade is still in the hands of the United States, the quantity sent over in 1895 being 749,258 tons, as against 55,078 tons of Russian origin.—C. S.

Gas Engines, Combustion of Lighting Gas in. F. Haber and A. Weber. Proc. Inst. Civil Eng. 126, (iv.), 51—56. From Habilitationsschrift für Chem. Techn. Hochschule, Karlsruhe, Nov. 1895.

TRIALS were made with two Otto engines, one being a 4 H.P. old-type motor with slide-valve and flame ignition, in which the governor acted by cutting off the gas supply, whilst the other was a modern 2 H.P. engine with lift valves and tube-ignition, the speed being regulated by diminishing the amount of gas. The gases were drawn off and examined chemically under varying conditions of work. The following conclusions are drawn:—That the combustion was perfect at full power in both engines, but less so at half power, CO, H, and CH₄ being then found in the products. The lubricating oil plays a small part in the combustion phenomena, and the water-jacket temperature has no influence. The explosive mixture on ignition burns in a few hundredths of a second, so that a low cylinder temperature cannot affect it; the gases being violently agitated when explosion occurs, are at a uniform temperature, which is that of the inner wall surface. An explosive mixture diluted to the limit of inflammability must have a low combustion temperature—so low that combustion is imperfect owing to some parts not being raised to their ignition temperature. If the flame spread so slowly that combustion may be followed by the eye, it is imperfect, and, in a gas engine, were the mixture uniform, the progress of the flame would be so slow that the engine would not work. The authors confirm Slaby's statement that the explosions in the cylinder are short and sharp because the mixture is imperfect, and contains strongly-, weakly-, and non-explosive particles. The last-named probably yield the combustible residuum as follows:—The suction-stroke begins when the compression-space is full of exhaust products, which expand into the space behind the receding piston, whilst the admission valves successively rise, so that air and gas enter.

These three strata become partly mixed during the compression stroke, but there is, even at the end, a strongly-explosive mixture near the ignition channel, and a weak mixture next to the piston. The less rich the mixture of gas and air, the further removed from the piston-surface is the limit of violent explosion, and the thicker the weakly- or non-explosive layers. Particles of lighting gas at high pressure and speed may possibly penetrate this layer, and, escaping ignition, would account for the presence of CH_4 and H in the exhaust. The presence of CO points to more complicated phenomena. The combustible residue in the exhaust of the lift-valve engine was thus probably due to the use of a small charge. In the slide-valve motor it may perhaps be explained by the weakness of the first explosion after miss-fires, as shown by the indicator diagrams. In the valve-engine, when running at half-power with the cock fully open, the first explosion of each series also often missed fire. Both engines showed the presence of combustible gases in the exhaust whenever the explosions were intentionally caused to be weak, and the two phenomena appear therefore to be intimately connected.—W. G. M.

Acetylene, The Explosion of, with less than its own Volume of Oxygen W. A. Bone and J. C. Cain. *Proc. Chem. Soc.* 1896, [169], 176—177.

CONTINUING their earlier experiments (*Proc. Chem. Soc.* 142, 170), the authors have exploded mixtures of acetylene with from 29 to 95 per cent. of its own volume of oxygen in a leaden coil some 5 m. long, having an internal diameter of 13 mm. The coil was closed at each end by a steel tap, and at one end a stout glass firing piece, into which two platinum wires were fused, was fixed between the steel tap and the end of the coil. The other end of the coil was connected with a mercury manometer, so that the pressure change inside the coil after an explosion could be determined.

The coil was immersed in a bucket of cold water, which served to rapidly cool the gases in the coil after an explosion. The coil was filled with the explosion mixture at the ordinary atmospheric pressure, by displacement; the mixture was then fired by an electric spark passed across the wires at the firing piece. After the products of the explosion had cooled down to the temperature of the water surrounding the coil, the tap nearest the manometer was opened, and the pressure of the gases inside the coil was read off. In all cases a considerable increase in pressure, varying from 360 to 370 mm. of mercury, according to the mixture exploded, occurred.

Samples of the products of explosion were collected and analysed; they were found to consist chiefly of CO and H_2 , but small quantities of acetylene and carbon dioxide were also present; methane was not present in "any appreciable quantity."

From these and the earlier experiments, the authors state that it is evident that when the electric arc is passed between carbon terminals in an atmosphere of hydrogen, acetylene and methane are both produced. Further, that the rate of formation of these two gases is fairly rapid during the first 15 minutes of the experiment, after which the rate falls, and finally, after about half an hour, a state of equilibrium between the hydrogen, acetylene, and methane is attained. This equilibrium depends, to some extent, on the voltage employed.

These results led to the inference that methane and acetylene would both be decomposed by the electric arc, and that if the arc is passed long enough a similar state of equilibrium would be arrived at. This conclusion was fully borne out by subsequent experiments, in which pure acetylene or methane was subjected to the action of the electric arc passed between carbon terminals in the same apparatus as that employed in the experiments with hydrogen.

Both methane and acetylene are easily decomposed by the electric arc; during the first 10 minutes of the experiment, the gas (methane or acetylene, as the case might be) was very rapidly resolved into its elements, large flakes of carbon being formed in the neighbourhood of the terminals. A smoky flame rose from the terminals and filled the upper part of the globe. At the end of about 10 minutes this extraordinary appearance subsided, after which the arc

presented the same appearance as in the case of the hydrogen experiments.

The principal product in each case was hydrogen with about 9 per cent. of acetylene, and small quantities of methane, nitrogen, and hydrocyanic acid. In the experiment with acetylene, a minute quantity of naphthalene was also formed.

Calcium Carbide, Price of. *Zeits. für Beleuchtungswesen*, 1896, 251.

THE Aluminiumindustrie-Aktiengesellschaft Neuhausen has taken over a large amount of utilisable water power at Rheinfelden, and is erecting a large works for making carbide. When the manufacture is begun, the present price of 40 pfennige per kilo. will be "somewhat reduced." The Elektrochemische Werke in Bitterfeld has also acquired water power in the same district for the same purpose.

—C. S.

Monazite, The Chemistry of the Constituents of. G. P. Drossbach. *Ber.* 29, [15], 2452—2455.

THE finely-pulverised monazite (from the Blue Mountains) was decomposed by sulphuric acid and extracted with cold water as usual, and after fractionating out the feebly basic thorium, strong sulphuric acid in large excess was added. On partly neutralising with sodium hydrate, the sodium sulphate formed caused complete precipitation of Ce , La , and Di as double sulphates; the metals of the erbium group were precipitated from the filtered solution by means of oxalic acid.

Separation of Cerium from Lanthanum and Didymium.—When permanganate is added to Ce_2O_3 (either in the form of hydrate, or in solution which is kept neutral), the latter is oxidised to CeO_2 , which is precipitated along with MnO_2 . In using this reaction to effect the separation, an aliquot part of the solution containing the Ce , La , and Di , was precipitated by ammonia, and the ceria titrated with permanganate solution. To the main quantity of solution was then added a slight excess of KMnO_4 , and the calculated amount of alkali, when the ceria precipitated quantitatively, and with it a didymium body. From the precipitate, slightly dilute nitric acid extracted most of the didymia; stronger acid thereafter extracted the ceria, leaving the MnO_2 , and the ceria solution was crystallised after adding ammonium nitrate to obtain the double salt.

Separation of Lanthanum from Didymium was effected by adding sodium hydrate solution to the La and Di (in solution as nitrates) until the supernatant liquor showed no absorption spectrum; the lanthanum in solution was thus free from didymium, and any lanthana contained in the hydrate precipitate was removed by digesting with red didymium solution.

The *Didymium body* which precipitated along with the CeO_2 differed from ordinary didymium, which shows a large number of absorption bands, by exhibiting only the narrow line to the left of D , and two strong, sharp bands to the right of D .

Separation of the Erbium Group.—After converting the above-mentioned precipitate of the oxalates into hydrates by means of potassium hydrate, and dissolving these in nitric acid, a double precipitation with magnesia left all the yttria in solution, the precipitate containing all the ytterbia, ceria, and probably a new oxide. If the last-mentioned precipitate is converted into nitrate and fractionally precipitated with sodium hydrate, the first fractions contain the ytterbia, which can only be recognised by its atomic weight and by its giving no absorption spectrum. Further gradual addition of very dilute sodium hydrate to the yellowish-red solution, until the supernatant liquor no longer showed the erbium absorption spectrum, gave in solution a colourless oxide having an atomic weight, calculated from the sulphate and assuming the formula to be R_2O_3 , of 98.5—100.5. The properties of this new body are: the sulphate is relatively easily soluble in water, only concentrated solutions giving crystals on heating; its solutions show no absorption spectrum; the oxalate is soluble in solutions of alkali oxalates; H_2O_2 and ammonia give a white precipitate (peroxide?); the carbonate and hydrate are easily soluble in excess of alkaline carbonate.

A solution in ammonium carbonate gradually deposits a precipitate of carbonate, but not if ammonia be added; the oxalate is soluble in carbonates. It differs from thoria in its strong basicity and the solubility of its double salts with alkali metals.—H. B.

Thorium, The Separation of, from the other Rare Earths by means of Potassium Trinitride. [*Incandescent Mantles.*] L. M. Denuis. J. Amer. Chem. Soc. **18**, [11], 947–952.

THE solution of potassium trinitride (KN_3) used was prepared by neutralising a dilute solution of hydrogen trinitride with a dilute solution of pure potassium hydrate, and then adding enough hydrogen trinitride to give the solution a distinctly acid reaction; it contained about 3.2 grms. KN_3 per litre. On adding a few c.c. of this solution to a neutral solution of a thorium salt and boiling for one minute, a white flocculent precipitate is obtained, which rapidly settles, the thoria being precipitated quantitatively as hydroxide, which may be filtered off, washed with hot water, ignited, and weighed as ThO_2 . The author's experiments with pure thorium in the form of chloride and of nitrate show that the process yields exact results. Solutions of pure lanthanum chloride and of the mixed chlorides of the rare earths from Brazilian monazite, previously freed from thorium, gave no precipitate with potassium trinitride solution; and when these solutions were mixed with various known quantities of a tested solution of thorium chloride, the author obtained, by the process indicated above, fairly exact separations of the thoria in all cases, the sharpness of the separation not being influenced by variations in the relative amounts of thoria and the other rare earths.

In considering what reaction takes place when thorium solutions are precipitated by means of potassium trinitride, it is evident that if it falls as ThO_2 , then all the hydrogen trinitride equivalent to the potassium salt first added must reappear in the filtrate from the thorium hydroxide and in the gas evolved during the boiling. The author proved this to be the case. 10 c.c. of the KN_3 solution used, gave with neutral silver nitrate solution a precipitate of AgN_3 , which, on washing with cold water, dissolving in hot dilute nitric acid, and precipitating with hydrochloric acid, produced AgCl equal to 0.0416 gm. HN_3 . 10 c.c. of the same KN_3 solution was used to precipitate a solution of thorium nitrate, the gases produced during the boiling being passed through an upright condenser into two absorption vessels containing neutral silver nitrate solution. After two minutes' boiling in this way the condenser was disconnected, the thorium precipitate filtered off, silver nitrate added to the filtrate, the silver trinitride precipitate produced added to that obtained in the absorption vessels, and the whole then dissolved in hot dilute nitric acid and precipitated with hydrochloric acid. The AgCl precipitate obtained, was equal to 0.0134 gm. of hydrogen trinitride, showing a little deficiency, doubtless due to loss of hydrogen trinitride by volatilisation, whilst filtering off the $\text{Th}(\text{OH})_3$ precipitate. The reaction is therefore correctly represented by the equation—

Thorium Mantles, The Influence of Foreign Oxides on the Lighting Power of. G. P. Drossbach. J. Gas Lighting, **68**, 1018.

IN trying to discover substances capable of forming efficient incandescence mantles without coming within the scope of the Welsbach patents, the author experimented with oxides of the heavy metals and with the alkaline earths. In a blowpipe flame the light-emitting value of the separate oxides was found to be according to the formula: (Mol. wt. \times sp. gr.) \div sp. heat; but the oxides were gradually reduced and vaporised in the flame. If, however, refractory oxides are introduced into the mantle with the reducible ones, in the author's opinion, the former act as bases towards the latter, and much better results are obtained than from the reducible oxides alone, especially if thoria, or another oxide having a high molecular weight, be employed as the base. Cr_2O_3 , TiO_2 , or WO_3 on the

one side gave excellent mantles with ThO_2 (containing traces of CeO_2); CaO , SrO , or ZnO on the other. As solutions of salts of the metals named, give precipitates with solutions of thorium salts, the cotton fabric is first steeped in the metallic salt solution, pressed and dried, and then further treated as usual with the thorium solution. The proportion of acid to basic oxides must be such that acid or neutral precipitates—not basic precipitates—are always formed in the mantle before burning off the cotton. The cotton fabric used should be washed previously in hydrofluoric acid, to remove the detrimental mineral matter which it usually contains.—H. B.

Incandescent Lamps, Method of Measuring the Temperature of. P. Janet. Comptes rend. **123**, 1896, 690–691.

THE resistance of the filament of a lamp varies greatly with its temperature. Suppose a difference of potential varying from 0 to E to be applied to the terminals of the lamp; for every value of E the temperature will take a value θ and the resistance a value R. We can construct a curve (A), having for abscissae R, and for ordinates $\frac{E^2}{R}$, i.e.

the power lost by radiation at the temperature θ . Now let the current be stopped at the time 0, and, as it cools, let the variation of the resistance of the filament be studied as a function of the time. Construct a curve (B), having for abscissae the times, and for ordinates the resistance R. By means of curve A we can deduce a third curve C, having for abscissae the times and for ordinates the power lost by radiation at each instant. The area of this curve gives the total energy lost by radiation from the maximum temperature of the filament down to the ordinary temperature: dividing by the mechanical equivalent of heat, we get the amount of heat which corresponds to this. Finally, if we weigh the filament and assume that certain data are known, we can deduce the temperature. The method enables us to investigate the variation of the resistance of the filament with temperature, and the variation of the radiation with temperature.

The data required have been supplied by Violle's determinations of the mean specific heat of carbon from 0 to temperatures above 1,000°. The above method further involves the assumption that the filament consists of pure carbon.—D. E. J.

Acetylene, Motor Force of. [*Gas Engines.*] Ravel. Journ. de l'Eclairage au Gaz, **4** (1895), 266–268.

EXPERIMENTS were made with a double-action, two horse-power gas engine. Alternate experiments were made with coal-gas for comparison and control. Preliminary experiments were made on the explosibility of acetylene.

At atmospheric pressure the lowest limit of explosibility is reached, when 1 vol. of acetylene is mixed with 0.71 vol. of air; the limit rises gradually with increasing proportion of air to the maximum at 1 vol. of acetylene to 12 of air, and then decreases till a mixture containing 1 vol. acetylene to 20 of air ceases to be explosive. Le Chatelier gives the rate of propagation of explosions in mixtures of acetylene and air as 0.18 metre per second in a mixture containing 2.9 per cent. of acetylene, rising to 5 metres for 5 per cent. of acetylene, and to the maximum of 6 metres for 10 per cent. of acetylene. The latter rate is far in excess of the maximum rate in mixtures of air and coal-gas.

The ignition temperature of acetylene is about 480° C., whilst that of ordinary coal-gas is about 600° C. The temperature of combustion of equal volumes of acetylene and oxygen is 4,000°, or about 1,000° more than that of the oxyhydrogen flame. The flame produced by the explosion of a mixture of air and acetylene under a pressure of $1\frac{1}{2}$ lb. on the square inch is of a brilliant yellowish-white colour.

The explosive force of mixtures of acetylene and oxygen or air, is much greater than that of similar mixtures of coal-gas or of hydrogen, and is almost of detonating character.

In working with acetylene, it is therefore most important to bear in mind (i.) the great rapidity of propagation of its

flame; (ii.) its very low ignition temperature; (iii.) the high temperature of its flame; and (iv.) its very high explosive force.

The acetylene was made from calcium carbide and supplied to the engine from a holder at 160–165 mm. of water pressure. The compression in the engine was regulated to 42.6 lb. on the square inch in some of the experiments, to 32 lb. in others. An accurate meter was placed between the holder and the engine. Owing to the high disruptive force observed in acetylene explosions, great precautions were observed, and only small percentages of acetylene used. When the percentage of acetylene in the cylinder exceeded 4 per cent., the explosion gave a hard metallic report, causing such violent shock to the engine as to be alarming, and to make the taking of diagrams difficult and uncertain, and in some cases impossible. The amount of lubricating material required when using acetylene is about double that required when using gas.

The results of the acetylene experiments are given in the following table. Graphic diagrams were also taken:—

No. of Experiment and of diagram.	Strokes of Engine per Minute.	Horse-power indicated.	Consumption of Acetylene per Hour in Cubic Feet.	Horse-power Generated per Cubic Foot of Acetylene consumed.	Percentage of Acetylene in Explosion Mixture.	Compression in Lb. per Square Inch.

The diagrams show that the initial pressure increases with the percentage of acetylene, but the fall of that pressure becomes concurrently quicker. Thus, at percentages of acetylene approaching 5, the initial pressure is almost dangerously high, but subsides instantaneously—a condition very much against efficient and economical working. The author considers that the explosive charge is subject to great internal vibrations during combustion. In order to lessen these vibrations as indicated in experiments 5 and 6, the author, in 7 and 8, increased the volume of the charge at the moment of ignition, i.e., decreased the compression and, as will be seen, thereby increased the effective work.

From the results given in the table, the author concludes that 1 cb. ft. of acetylene in a two horse-power gas engine produces a work on the piston of 320–325 horse-power. In the same engine the normal consumption of coal-gas is 33.7–34.4 cb. ft. per hour for 1 indicated horse-power.

The consumption per hour per effective horse-power (French, i.e., 0.985 horse-power English) of acetylene at 160 mm. water pressure, would be $385.7 \text{ kilogr. metres} \div 850 = 453 \text{ litres}$, which equals 460 litres at atmospheric pressure and weighs 550 grms.

In larger engines the effective power would probably be higher, but the ratio between that of acetylene and of coal gas would probably remain the same.

The author does not believe that the high explosive force of acetylene can be effectively utilised in the present form of gas engine. For either the acetylene must be used in considerable proportions in the explosive mixture, and then only gives a small part of its real power, owing to the suddenness of the explosion, or the dilution with air must be so great that the heating power of the acetylene is not enough to heat the whole mass of the mixture sufficiently to give by expansion the full power under economical conditions. Possibly better results may be obtainable in a rotary or turbine form of engine.—L. T. T.

Acetylene, Use of, in Gas Engines. A. v. Ihering. Journ. f. Gasbeleucht. 39, (1896), 685–687.

THE author gives the substance of Ravel's paper (see preceding abstract) and discusses the results therein

published. He believes that with a quadruplex engine better results may possibly be obtained than with the double-action one used by Ravel.

Taking the mean of Ravel's first four experiments, 380 litres of acetylene are required per hour per horse-power against 950 litres of coal-gas; the ratio value of acetylene to coal-gas would thus be about 2.5:1. Using a 5 H.P. engine the author found 303 litres of acetylene produce 1 I.H.P., and the ratio of acetylene to coal-gas as 2.7:1, showing that the effectiveness is greater in large engines than in small.

Reckoning the cost of calcium carbide as 150 marks per 1,000 kilos. (about 7l. 12s. per ton) and the yield of acetylene as 300 litres per ton of carbide, and taking Ravel's figures of 380 litres of acetylene, or 950 litres of coal-gas, per I.H.P. (French), the cost per H.P. would be for acetylene 19 pf. (2.38d.), and for coal-gas 11.4 pf. (1.43d.); coal-gas being reckoned at 12 pf. per cb. m. (3s. 4d. per 1,000 cb. ft.). Coal-gas is thus only about two-thirds the cost of acetylene as a motive power.—L. T. T.

PATENTS.

Coke, Porous [from Coal with admixed Sawdust], New Process for Making. O. Heimaun, Oppeln, Germany. Eng. Pat. 23,051, Dec. 2, 1895.

To diminish the density and increase the porosity of the coke produced from pit coal the inventor proposes to mix with the coal, from 1 to 90 per cent. of sawdust, wood-chips, spent-tan, or other finely-divided vegetable matter, which, it is said, prevents the coal from caking and shrinking in bulk to the same extent as when employed alone, the copious evolution of gases during the combustion of the added vegetable substances also rendering the coke more porous.—C. S.

Gas Liquor Separators, Impts. in. S. Cutler, Millwall. Eng. Pat. 24,383, Dec. 19, 1895.

The separator consists of a long chamber with a trough-shaped bottom sloping towards one end. The liquids from the gas washer are admitted at the shallow end and pass a series of transverse baffles, whereby the tar and heavier liquids are caused to settle down into the trough and flow into a separate division at the deeper end of the chamber, the water being drawn off through a sump. Gauges are provided to show the level of the liquids.—C. S.

Gas Carburetters, Improved Oil Atomiser for. S. Cutler, Millwall. Eng. Pat. 24,384, Dec. 19, 1895.

The apparatus consists of a tube descending into the carburetter. It is fitted with a nozzle at the lower end and contains a core-rod terminating below in an inverted cup, perforated with a series of oblique holes and fitting tightly in the pipe. The oil entering the pipe under pressure is atomised by passing through the apertures, the spray gyrating at a high rate of velocity in the cup and issuing from the nozzle, and the area of the spray is controlled by raising or lowering the cup, an operation performed by the aid of a screw or other device at the upper end of the core.—C. S.

Regenerative and other Furnaces [Liquid Fuel, and injecting Compressed and Heated Air], Impts. in. L. Moyes, Glasgow. Eng. Pat. 24,664, Dec. 24, 1895.

THE inventor proposes to inject compressed heated air into the furnace (for oil or liquid fuel) described in Eng. Pat. 13,761 of 1894 (this Journal, 1895, 21), in cases

where superheated steam is found unsuitable. The air blast may be supplied by any suitable means, and at any desired temperature and pressure (30 lb. per square inch will, in general, give good results), the size of the pipes employed being adapted to the conditions prevailing in this respect.—C. S.

Generator Gas, Impts. in Apparatus for. [*Direction of Steam and Air Jet through centre of Fuel, &c.*] J. E. Dowson, Westminster. Eng. Pat. 6919, March 30, 1896.

THE improvement consists in reducing the area of the grate or firebar space in the bottom of the generator, so that the steam and (or) air blown in through the grate may ascend through the centre of the fuel. By this means less clinker is formed around the lining of the generator, and a gas of improved heating power can be produced with inferior fuel.

In the case of fuel softer than anthracite or coke, the upper part of the generator is fitted with an internal shell of iron (down to the level where good gas can be drawn off), the interior of which is filled with fuel, leaving an annular space for the withdrawal of gas of good quality. The fuel in the upper part, being heated by the fuel below and the hot gases in the annular space, evolves condensable vapours, which are exhausted through an aperture in the top by the steam or air blast, and are conveyed thereby into the space below the grate, and thus into the lower part of the generator, where they are burnt or converted into fixed gases.—C. S.

Burners for Gasifying and Burning Hydrocarbons [*Lumps fed with Light or Heavy Hydrocarbons*], chiefly designed for the Production of Light by Incandescence; Impts. in. S. Marcus, Vienna, Eng. Pat. 16,735, July 28, 1896.

THE mouth of the burner-tube is closed by a small dome of wire gauze, and the rim of the tube is toothed, corrugated, or perforated, and projects over the base of the flame for the purpose of exposing a great contact surface to the flame, that the heat may be conducted to the vaporising chamber. The latter comprises a hollow ring or annular piece (arranged outside or inside, near the mouth of the burner) in which terminate two tubes, one of which leads the liquid fuel up into the vaporising chamber, and the other conducts the generated gas downwards to a nozzle placed centrally within the burner-tube. The gas, on issuing upwards from the nozzle, draws in air through the wall of the burner-tube, which is provided with longitudinal slits, the outer casing being supplied with similar slits. The upper part of the burner tube may be divided into mixing chambers by interposing diaphragms of wire gauze in the path of the current of air and gas. In the special form of burner for light hydrocarbons, the vaporising chamber simply consists of a chamber at the base of the burner, near the point at which the liquid passes the entrance valve, and communicating directly with the nozzle, no conducting tubes being then necessary.—H. B.

Acetylene Gas, Improved Apparatus for Producing, Storing, and Utilising. G. Trouvé, Paris. Eng. Pat. 23,521, Dec. 7, 1895.

THE gas generator comprises a stoppered vessel immersed in a second vessel containing water, the former vessel having an aperture at the bottom and enclosing a suspended wire cage containing calcium carbide crystals. The crystals are arranged in superposed layers, separated by glass discs, to cause the successive immersion of the layers and ensure a uniform production of the gas. One or more generators may be connected to a holder for storing the gas. A portable lamp, consisting of a generator provided with a burner and fittings, is also described, the generator being connected to the burner by two concentric tubes, one for conveying the gas and the other for siphoning off the condensed water. In a modification, the concentric tubes are replaced by a spiral metal strip enclosed in a box through which the gas passes, the strip serving to condense and collect the aqueous vapour.—R. A.

Acetylene Gas Generators, Impts. in or connected with. W. W. R. Warn and L. F. King, both of Poole, Dorset. Eng. Pat. 75, Jan. 1, 1896.

THE generator consists of inner and outer chambers, having a space between them filled with water under pressure, a revolvable table mounted within the inner chamber and carrying a number of cells containing calcium carbide, &c., and pipes for supplying the water to the cells. These cells are filled with calcium carbide and stone lime, ("the latter to prevent smoking"), and suitable taps operated by means of rods are provided to control the supply of water to the cells. A grid placed above the cell is adapted to contain lime or other suitable desiccant for drying the gas. The apparatus is also provided with suitable gauges, &c. The generation of the gas is regulated according to the amount consumed, as the supply of water to the cells is checked or increased according as the pressure of the gas rises above or falls below that of the water.—R. A.

Gas [Acetylene, &c.] Generating Apparatus, Improved. A. J. Boulton, London. From H. F. Fuller, Chicago, U.S.A. Eng. Pat. 19,288, Sept. 1, 1896.

THE apparatus is a gas-holder constructed on the principle of intermittent contact of the solid gas-generating material with the sealing liquid, the volume of the liquid, and therefore the weight of the apparatus, being lessened by turning up the walls of the outer vessel inward, so as to form an annular space into which the gas-holder cover dips. In the upper part of the cover is fitted a perforated plate on which the carbide is laid, a reserve supply—which also serves to dry the evolved gas—being inserted both in a basket placed over an opening in the cover and in an upper chamber surmounted by a second (smaller) gas-holder containing the outflow tap. The waste lime is caught in a receiver placed on the raised bottom of the outer vessel, and the prevention of overflow from the latter by reason of the displacement of the sealing liquid (in this case water), by the waste lime, is secured by raising the height of the external walls. It is furthermore claimed that this construction ensures regularity of pressure during the working of the apparatus.—C. S.

Acetylene Gas, Impts. in and relating to a Method of and Apparatus for Producing. J. A. Denthier, Boston, U.S.A. Eng. Pat. 20,599, Sept. 17, 1896.

THE calcium carbide or other gas-generating substance is made in the form of tablets, which are stored in a hopper above a reservoir containing water, &c., the tablets being fed singly from the hopper into the reservoir by means of a reciprocating slide connected through suitable levers to, and operated by the bell of the gasometer, &c. As the bell falls, a fresh tablet is fed into the reservoir, and a fresh quantity of gas generated, the supply of gas being thereby automatically regulated according to the consumption.—R. A.

Acetylene Gas, Apparatus for the Production of. W. B. Rickman, 38, Leadenhall Street, London. From J. Pintsch, Berlin. Eng. Pat. 20,602, Sept. 17, 1896.

THE apparatus consists of a closed receptacle containing water, and provided at its lower end with a horizontal grating, on to which the calcium carbide is fed in lumps through a hopper at the side. Water is also supplied through the hopper, and is maintained at a constant level within the receptacle by means of an overflow pipe which is closed by a water seal. The grating is mounted on pivots, and can be oscillated by a handle from the outside, to prevent it from becoming clogged.—R. A.

Acetylene Gas, Impts. in Apparatus for the Manufacture of. V. Sardi, Turin, Italy. Eng. Pat. 20,903, Sept. 21, 1896.

THE apparatus consists of a gas generator and a gas holder, the former being mounted on or connected to the bell of the latter. The calcium carbide is contained within a perforated cylinder having a rod which passes through a gland in the top of the generator, this top being formed by a bell sealed to the body of the cylinder by a water joint.

In operation, the generator sinks with the bell of the gas holder as the gas is consumed, until the carbide comes in contact with the water contained in the gas holder, when a fresh supply of gas is generated, which again raises the bell and the generator until the carbide is clear of the water. The perforated cylinder can be removed and recharged with the carbide without stopping the supply of gas from the gas holder.—R. A.

Acetylene Gas, Impts. in Generators for. S. Kon, Warsaw, Russia. Eng. Pat. 21,468, Sept. 28, 1896.

The gas generator is affixed to the outside of the water reservoir of the gas holder, from which it is supplied with water. The calcium carbide is contained in a perforated cylinder having a rod which passes through a stuffing-box in the top of the generator, the rod being provided with stops which engage a pair of spring arms on the bell of the gas holder, so that the carbide is immersed in or removed from the water as the bell of the gas holder sinks or rises. When the generation of the gas is excessive, the spring arms are forced apart by a releasing device, so that they pass over the upper stop. For the purpose of mixing the gas with air, a cylinder supplied with air from the outside is affixed within the bell of the gas holder, the air passing from this cylinder through a U-tube to the annular space between the cylinder and the bell, into which space the gas from the generator is also delivered.—R. A.

Vapour Burners for Heating Purposes, Impts. in. H. Kretschmann, Berlin. Eng. Pat. 19,352, Sept. 1, 1896.

The patentee claims a heating burner, fed with liquid fuel, the main feature of which is that, above or below a gasification chamber wherein the liquid fuel is converted into gas, there is arranged a chamber wherein the gas and air mix, and are superheated; from this last-mentioned chamber there descends a length of tube, the object of which is to "receive the gas jet or current supplied from the gasification chamber, together with the air carried along by such current or jet, and to deliver both the gas and the air, through lateral apertures," into the mixing and superheating chamber. The mixture issues in an annular flame on all sides of the lower part of the mixing (superheating) chamber, the flame serving to heat both the mixing and gasifying chambers.—H. B.

Incandescent Gas Burners, Impts. in. [Superheating Air, and Gas Mixture.] P. Bode, Berlin. Eng. Pat. 19,973, Sept. 9, 1896.

The short Bunsen tube is provided with more air-holes than usual, and the perforated part of the tube is surrounded by a grid with inclined slots, the object being to cause the air which is drawn in to take an inclined direction. Concentric with the Bunsen tube and surrounding its upper part is a tube (1), which is closed by a plate a short distance above the mouth of the Bunsen tube, and which has outlet slots at its lower part. Concentric with and surrounding tube (1) is a tube (2) closed at its lower end. The mixture of gas and air issuing from the mouth of the innermost (Bunsen) tube passes downwards through the annular space between the latter and tube (1), flows through the slots at the base of tube (1), and again flows upwards in the annular space between tubes (1) and (2). The burner rim, at which the gas is burned, consists, instead of wire gauze, of two concentric fluted or corrugated ring inset pieces, separated by a ring-shaped, non-corrugated partition and having a central socket to hold the carrier of the mantle. The gas and air mixture in its zig-zag passage through the tubes receives a preliminary heating and becomes intimately mixed.—H. B.

Incandescent Lighting [Alcohol or Hydrocarbon Lamps], Portable and Hygienic, wherein the Evaporation of Hydrocarbons is produced under Pressure. G. Musso, Naples. Eng. Pat. 13,648, June 20, 1896.

ARRANGED in a circle are a number of tubes containing wicks which dip into a reservoir containing alcohol, or gasoline, or other liquid hydrocarbon. These tubes at the upper end are joined to a small "evaporating chamber," into which the wicks project slightly, and in the centre of

the circle of tubes is a lamp, the flame of which plays on the bottom of the evaporating chamber, and to some extent on the upper ends of the tubes, vaporising the hydrocarbon which has been drawn up by the wicks inside. A small portion of the vapour thus produced is led off through a side pipe to supply the lamp above referred to, the size of the flame being regulated by the gas itself on passing through a spring needle governor. The main body of the gas passes at a considerable pressure through a small conical nozzle into an upright tube, the latter being perforated with air-holes near its base and acting as a Bunsen burner. To promote the thorough mixing of the gas and air, a perforated diaphragm is fixed inside the burner tube at its upper part, the mouth of the burner being fitted with a small perforated dome. The rod, which serves to support the mantle, is fixed into a socket in the centre of the perforated dome and diaphragm, and the asbestos thread of the mantle is fastened to the fork of the support by means of a mixture of chalk and silicate of potash.—H. B.

Mantles for Incandescent Burners, Improved Process of Manufacturing. [Impregnating before Weaving.] H. Wellstein, Berlin. Eng. Pat. 19,357, Sept. 9, 1896.

IN order to obtain mantles having a more even distribution of the oxides on their peripheries than have hitherto been made, the patentee impregnates thread-like material of suitable thickness with a solution of the suitable salts ("more particularly thorium oxide, with eventually the addition of other suitable metallic oxides"), afterwards knitting or weaving the thread to form tubular mantles.—H. B.

Gas for Artificial Lighting and Motive Power Purposes, Impts. in and Apparatus for the Production or Generation of. A. Devis, Charleroi, Belgium. Eng. Pat. 19,830, Oct. 22, 1896.

A DOME-TOPPED cylinder, somewhat like a small gas holder in form, works in a receiver containing water. On opposite sides of this cylinder are two pistons in long cylinders, the piston rods being connected at their upper ends to the crown of the dome-topped cylinder, and forced upwards by water pressure in such a way as to carry the cylinder with them; the latter during its ascent, sucking in air by a valve on the top of the dome, which closes automatically at the same time as the water pressure is relieved. On opening the water-escape valve, the pistons drop, along with the cylinder, and the air is blown out by a stand pipe inside the cylinder, the head of which is above the water level.

The air passes into a second receiver, in the lower part of which are a number of superposed trays communicating with one another and containing petroleum "or any other rich mineral oil." Each tray is connected to a tap outside the vessel, which serves for introducing the petroleum, &c., and in each compartment, about 4 inches above the surface of the petroleum, is a perforated tin shelf supporting a layer of cotton waste. The air bubbles through the petroleum in each tray successively, the carburetted air filtering through the layers of cotton waste, and being then passed upwards through a stand-pipe into a dome-topped gas-holder working in a vessel of water in the upper part of this second receiver.—H. B.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

Oil and Ozokerite Deposits in Russia. J. Soc. Arts, 1896, 44, 859.

THE oil which is found in the island of Teheleken, in the Caspian Sea, is stated to be forced to the surface by numerous springs of hot "sulphur water" (102° F.), and accumulates in wells. Analytical tests made in the laboratory of the Technical Committee of Baku have shown that the crude oil is of thick consistency at 9° C., and becomes solid at a little below 0° C. The water in it is difficult to remove, and this circumstance proves a serious obstacle in the distillation. Its specific gravity at 15° C. is 0.868, and its flashing point 51.5° C. A characteristic of the oil is its high content of paraffin (5.5 per cent.).—A. S.

Asphalt, Mining and Preparation of, at Lobsann. Jasper. Zeits. f. Berg-, Hütten- u. Salinen Wesen, **44**, [4], 387—392.

ASPHALT rock has been worked at the Lobsann brown coal concession ever since 1820, but not to any great extent, owing partly to lack of demand for the products and partly to prolonged litigation with the neighbouring petroleum concession at Pechelbroun.

The deposit extends eastward of the great fault separating the younger geological formations of the Rhine plain from the Vosges red sandstone rock, and consists of four layers of fresh-water lime impregnated with bitumen. These strata are interspersed with limestone containing no bitumen, and are situated in a brown coal deposit some 30 to 40 metres in thickness, of the volume of which they compose some nine-tenths. The percentage of bitumen ranges from 8 to 11 per cent., the richest layers yielding up to 18 per cent.; and the consistency of the rock varies, some being soft and easily extracted with the pick, whereas other portions are very tough and can only be got out by blasting. The bitumen itself is so strongly adherent to the particles of lime that (unlike the pitch sand) it cannot be extracted by boiling with water.

A hauling way, driven at a slight incline for a distance of 60 metres from the bank, leads to the workings, which have been opened up by sundry cross-headings and galleries, most of the asphalt hitherto obtained having been derived from the *déchets* of these development works, so that it is calculated there is at present an accessible reserve of fully 3½ million tons of asphalt rock ready for working, a quantity sufficient to last for 100 years, even by increasing the present output tenfold.

The crude rock is dried and heated by steam in vertical cylindrical iron retorts, to render it more readily pulverisable in the mills and disintegrators.

This asphalt powder is partly sold as such and partly made up into mastic ("asphalt mastix") by admixture with 10 per cent. of pure natural Trinidad asphalt, or—as has been found to give equal results at less cost—with 6 per cent. of Alsation petroleum residue (flashing above 220° C.) and 4 per cent. of Trinidad asphalt previously melted and filtered. The materials are incorporated by stirring together in horizontal semi-cylindrical iron vessels for 12 hours at 160° C. to 170° C., and the mass is cast into blocks weighing about ½ cwt. apiece.

A third product—"asphalt comprimé" powder—is prepared from hand-picked rock, containing on an average more than 13 per cent. of bitumen, dried and ground twice, and packed in sacks. For use, this powder is heated to 120° C. in iron ovens and spread over the surface to be paved, where it is compressed by hot rammers and smoothed irons.

The "asphalt goudron"—another product—consists of 70 per cent. of filtered Trinidad asphalt and 30 per cent. of Alsation petroleum residue, fused and mixed during 48 hours, and, after standing for the separation of earthy impurities, packed in casks.

For small sections of paving (footways, &c.) and places where the smell of hot asphalt is objectionable, "asphalt comprimé" slabs are made 3—5 cm. thick, in moulds under 150 to 180 atmospheres pressure.

The total output has varied of late considerably, between 8,000 and 11,000 tons per annum from 1878 to 1882, sinking to 704 tons in 1889, and averaging 3,208 tons from 1892 to 1895, during which period 50 to 60 hands were employed. Germany forms the sole market for the products, and until recently foreign asphalts have been preferred by the various municipal and other authorities—a condition of things that militated against any extension of output, but which is now fast disappearing.—C. S.

Coal-tar Thioxen. K. Keiser. Ber. 1896, **29**, 2560—2564.

THE experiments described were undertaken in order to determine whether coal-tar thioxen contains different isomers, of which there are four theoretically possible. With this object the author converted the crude thioxen first into a monobromo derivative; this he sulphonated, treated with sodium amalgam to remove the bromine, and

finally converted the product into sulphonie amide. By crystallising the latter from water, it was found to consist of various isomers. Two of these are shown by analysis to be different thioxen-sulphonie amides, and a third was found to be identical with the sulphonie amide obtained from synthetic thioxen. A fourth substance was also obtained, but its composition could not be determined.—A. K. M.

Durene-carboxylic Acids. V. Meyer and L. Wöhler. Ber. 1896, **29**, 2569—2573.

IN view of the incorrect statements recently made by Claus regarding the properties of the durene-carboxylic acids (J. prakt. Chem. **52**, 529), the authors have re-investigated them. They confirm Gattermann's statement that, under certain circumstances, the introduction of the carboxyl group into solid durene is accompanied by a partial rearrangement of the methyl groups, with formation of Prehnitic acid; but they also find that when the quantity of aluminium chloride is diminished, and only a short time allowed for the reaction, this intramolecular change does not occur, and the carboxylic acid derived from solid durene is alone formed. It is also shown that, whilst Prehnitic acid readily forms ethers, the corresponding acids derived from durene and iso-durene do not.—A. K. M.

PATENT.

Solidified Petroleum, Impts. in the Manufacture of. [Wool-Fat Acids, Heat, and Caustic Alkalis.] M. Ekenberg, Stockholm. Eng. Pat. 16,541, July 25, 1896.

THE improvements claimed are: the addition of fatty acids of wool-fat to petroleum or petroleum distillates, heating the mixture to a temperature of 120°—200° C., and then adding hydrates of alkalis or alkaline earths, or by dissolving in petroleum or petroleum distillates anhydrous soaps previously prepared from wool-fat, fatty acids, and alkalis or alkaline earths. The temperature of the mixture must not be below 120° C. during the addition of the hydrates, and the fatty acids should not contain any glycerides. From 1 per cent. to 15 per cent. of the fatty acids may be added, according to the consistency required in the resulting product, which, when thus prepared, is an anhydrous, transparent, and homogeneous substance.—W. P. S.

IV.—COLOURING MATTERS AND DYES.

Colours, The Examination of, and their Appearance under Artificial Illuminants. D. Paterson. J. Soc. Dyers and Colourists, 1896, **12**, 191.

THE artificial illuminants, arranged according to their respective colour-matching qualities, may be given as follows:—(1) Magnesium light; (2) electric arc light; (3) "Welsbach" light; (4) acetylene gas and lime light; (5) good oil lamp, coal-gas, electric glow lamp, candles.

The modifications of hue seen under artificial light depend upon the impurity of the light used and the nature of the absorption spectrum given by the colour. There are, however other causes which affect, in a very slight degree, such changes; these are *dichroism* and *fluorescence* possessed by the colours themselves, also the optical properties of the fibres. The chemical composition of the fibre does not appear to have any effect, but the *physical* or *optical* structure has a decided influence in such modifications of hue. Colours dyed on a fibre of good lustre and transparency, such as silk, China grass, or the finer qualities of jute, appear brighter and more enhanced, and of richer quality, in artificial lights.

Colours which to the eye match each other closely, yet present different absorption spectra, behave differently when viewed in artificial light. Colours possessing absolutely the same absorption spectra and properties behave identically under different illuminants.

The chemical constitution of the colouring matter, it is said, in no way affects such alterations in hue in artificial light.

Colours, though obscured in combination with other colouring matters, still preserve their individuality of character and behaviour towards these illuminants.—A. S.

The Phthaleins. II. R. Meyer and H. Meyer. Ber. 29, 2623—2626.

In a previous paper (Ber. 28, 1576; this Journal, 1895, 860) it was shown that the hydroxyls in fluorescein are symmetrically placed, and in the present paper a similar symmetrical formula is proved for the eosines. Baeyer (Annalen, 183, 25) has already shown that fluorescein when treated with fused potash decomposes into resorcinol and dihydroxybenzoylbenzoic acid. This latter, when heated above its melting point, gives off phthalic anhydride, reforming fluorescein. The reaction takes place in such a way that one molecule of dihydroxybenzoylbenzoic acid splits up into phthalic anhydride and resorcinol, and the latter then combines with a second molecule of the acid. This, however, affords no evidence of the symmetrical constitution of fluorescein, since the replacement in the resorcinol molecule could take place either *o-p* to both hydroxyls or between them. It is, however, otherwise with the dibromodihydroxybenzoylbenzoic acid obtained from eosine, for which Heller has shown that the substituents in the resorcinol residue have the following positions, $(\text{OH})_2 : \text{Br}_2 = 1:3:2:4$, and thus the position between the hydroxyls is occupied. If therefore eosine can be obtained from its decomposition product, dibromodihydroxybenzoylbenzoic acid, as fluorescein is from the non-brominated acid, its symmetrical constitution is proved, and this was found to be the case. The dibromodihydroxybenzoylbenzoic acid was obtained by heating commercial potassium eosine with twice its weight of 50 per cent. caustic soda lye to 140°C . until the blue colour of the melt changed to brown. The whole is then poured into ice-water, and slowly neutralised at a low temperature. On crystallisation from glacial acetic acid the acid melts at 224°C . When heated with one-fifth its weight of zinc chloride for 20 minutes to $235^\circ\text{---}240^\circ \text{C}$. it gives a good yield (87 per cent.) of eosine, which is identical in every particular with the substance originally started with. A red by-product which on reduction and oxidation gave fluorescein is formed simultaneously. The reaction expressing the formation of eosine takes place according to the following scheme:—

and since the phthalic acid residue certainly does not enter meta to the hydroxyl, the symmetrical formula for eosine may be considered as fully proved.—T. A. L.

The Phthaleins. III. R. Meyer and H. Meyer. Ber. 29, 2627—2640.

THE authors, in continuation of their work on hydroquinone phthalein, have examined the orcinolphthaleins as compared with ordinary fluorescein. The condensation of orcinol with phthalic anhydride only takes place in presence of a condensing agent, and three products are formed which have the following formulae:—

In order to distinguish these three products it is proposed to call that one α which dissolves in alkali with a carmine-red colour, β the one which is soluble in alkali with a cherry-red colour, whilst the fluorescent compound is termed γ . The α and β compounds are obtained in about equal quantities by the use of condensing agents such as sulphuric acid, zinc chloride, tin tetrachloride, phosphorus pentoxide, or ferric chloride, whilst a relatively larger quantity of the γ -isomeride is obtained by the use of vitreous phosphoric acid. The three compounds can be separated by their different behaviour to alkalis. The α product is insoluble in ammonia and carbonates, but soluble in potash; the β compound is soluble in carbonates, but not in ammonia sesquicarbonate; whilst γ -orcinolphthalein combines with ammonia vapour, forming an easily soluble ammonium salt, although the separation by these methods is by no means a perfect one. In addition to orcinol (dihydroxytoluene, $\text{CH}_3 : (\text{OH})_2 = 1:3:5$), the following compounds have been examined regarding their behaviour in the fluorescein reaction. Cresorcinol (dihydroxytoluene, $\text{CH}_3 : (\text{OH})_2 = 1:2:4$) gives on fusing with phthalic anhydride a compound analogous to fluorescein, which is converted by bromine into an eosine. The fluorescein reaction is also given by dihydroxytoluene ($\text{CH}_3 : (\text{OH})_2 = 1:2:6$), by dihydroxy-*m*-xylene [$(\text{CH}_3)_2 : (\text{OH})_2 = 1:3:2:4$], and by dihydroxy-*o*-xylene [$(\text{CH}_3)_2 : (\text{OH})_2 = 1:2:3:5$], whilst β -orcinol (dihydroxyxylene, $(\text{CH}_3)_2 : (\text{OH})_2 = 1:4:2:6$) does not give a fluorescein when fused with phthalic anhydride, but in presence of sulphuric acid, a compound similar to E. Fischer's orcinolphthalein. Di-iso-amylresorcinol gives no fluorescein, whilst *m*-xyloresorcinol [$(\text{CH}_3)_2 : (\text{OH})_2 = 1:3:4:6$] and mesoresorcinol [$(\text{CH}_3)_2 : (\text{OH})_2 = 1:3:5:2:4$] gives tarry melts with phthalic anhydride alone; in presence of sulphuric acid a fluorescent condensation product is obtained, which, however, is also formed in the absence of phthalic anhydride. Thus, except in the case of β -orcinol, the formation of fluorescein has been observed in all *m*-dihydroxybenzenes containing free positions *para* to one and *ortho* to the other hydroxyl. Certain substituents appear to modify or entirely remove the capability of fluorescing, and this may be an explanation of the behaviour of hydroquinone phthalein, which, although it shows no fluorescence, must undoubtedly be a dihydroxyfluorane. The experimental part of the paper is chiefly concerned with an examination of the properties of the three orcinol phthaleins, which can be separated to a certain extent, as already mentioned, by their different behaviour to alkalis.

α -Orcinolphthalein crystallises from glacial acetic acid in colourless crystals. The product has very feeble acid properties, since it can be extracted by ether from its solution in very dilute caustic potash. When brominated in glacial acetic acid, tetrabrom- α -orcinolphthalein is produced, and separates in yellowish needles, soluble in caustic soda lye with a violet colour, which on heating turns blue, but returns on cooling. Reduction of the phthalein with caustic soda lye and zinc dust yields the corresponding phthalin (m.p. 256°C), which gives a diacetate melting at 219°C .

β -Orcinolphthalein separates either in brownish needles or orange plates from alcohol. It yields a diacetate melting at 228°C , and a dibenzoate, m.p. 245°C , and when reduced with zinc dust and caustic soda lye gives a white precipitate of the phthalin, which is readily oxidised by potassium ferricyanide or permanganate to the phthalein. Tetrabrom- β -orcinolphthalein is in no respect a dyestuff. It dissolves in sodium hydrate or carbonate with a greenish-black colour, which in very dilute solutions is dirty red by transmitted

light, but it is not acted on by ammonia vapour, and may therefore be easily separated from its isomerides by this treatment.

γ-Orcinolphtalein is separated by means of the action of ammonia vapour on the crude product obtained by the action of phthalic anhydride on orcinol in presence of phosphorus pentoxide. The substance dissolves easily in alcohol, methyl alcohol, and glacial acetic acid, and has a great similarity to fluorescein. It dissolves in caustic alkalis, ammonia, and carbonates, with a brown colour and a green fluorescence. It dyes silk yellow, and dissolves on warming in sodium phosphate to a fluorescent solution, which is not decolorised by shaking with ether (difference from *β*-orcinolphtalein). When boiled with acetic anhydride it forms a colourless diacetate, melting at 208° C., which is easily hydrolysed. Reduction with zinc dust and caustic soda lye yields a colourless phthalin, whilst bromination in acetic acid gives tetrabrom-*γ*-orcinolphtalein or homo-cosine. This substance is sparingly soluble in all solvents, but separates from nitrobenzene in brownish prisms. It dissolves readily in caustic alkalis and in carbonates with an eosine-red colour. The solutions do not fluoresce, but appear yellowish-red by reflected and pink by transmitted light. Silk is dyed red similar to eosine, but the colour is not so strong. When heated with caustic soda the compound is decomposed in a manner evidently analogous to that in the case of eosine into dibromoresorcinol and dibromodihydroxybenzoylbenzoic acid. A more characteristic reaction of this homo-cosine is its behaviour to sodium amalgam and water. The prolonged action of these reagents, just as in the case of eosine, produces a colourless solution in which potassium permanganate gives a brown coloration and a dark green fluorescence. Hence, like eosine, nascent hydrogen removes bromine and produces a phthalin.—T. A. L.

Colouring Matters occurring in Various British Plants.
Part I. A. G. Perkin and J. J. Hummel. Proc. Chem. Soc. 1896, [169], 185—186.

FORMERLY numerous British plants were employed in dyeing, and at present in remote districts, notably the Highlands of Scotland, some are still used for this purpose. Many of these have been found sufficiently strong in colouring matter to warrant their chemical examination.

The Colouring Matters of the Yellow Wallflower. Cheiranthus cheiri.—An aqueous extract of the flowers when digested with acid, deposits a precipitate of colouring matter; this was found to consist of two substances which could be separated readily, owing to the difference of their solubilities in alcohol. The more soluble product, which was obtained as yellow needles, had the formula $C_{15}H_{10}O_7$, yielded an acetyl compound, $C_{15}H_8O_7(C_2H_5O)_2$; colourless needles, m.p. 189°—191°; when decomposed with fused alkali, protocathecinic acid and phloroglucin were produced. It was found to be *quercetin*.

The Sparingly Soluble Colouring Matter. $C_{16}H_{12}O_7$, minute yellow needles, gave an acetyl compound, colourless needles, melting at 195°—196°, and when acted upon by hydriodic acid, it yielded *quercetin*, and one molecule of methylic iodide. It was thus a *quercetin monomethyl ether*. Though closely resembling rhamnetin, it is not identical with it, for acetylramnetin melts at 184°—185°; and for it, is proposed the name *isorhamnetin*.

The Colouring Matter in White Hawthorn Blossoms. Crataegus oxyacantha, was obtained as yellow needles having the formula $C_{15}H_{10}O_7$. Its acetyl compound, colourless needles, melted at 189°—191°, and when fused with alkali, phloroglucin and protocathecinic acid were formed. There could be no doubt as to its identity with *quercetin*. It is most probable that these colouring matters exist in the above plants as glucosides. This point will be studied at a later date.

Natural Yellow Colouring Matters. Acid Compounds of.
Part II. A. G. Perkin. Proc. Chem. Soc. 1896, [169], 167—168.

IN a previous communication by Perkin and Pate (this Journal, 1895, 745), it was shown that when treated with mineral acids in presence of acetic acid, quercetin, ram-

netin, rhamnazin, fisetin, and morin, yielded crystalline compounds, the formula of which is generally represented as an addition product of one molecule of acid to one molecule of colouring matter. It has since been shown that luteolin and myricetin behave similarly, and there can be little doubt that all these colouring matters belong to the so-called quercetin group. In this paper certain of these compounds not previously examined are described, viz.: quercetin hydrochloride, $C_{15}H_{10}O_7.HCl$; morin hydriodide, $C_{15}H_{10}O_7.HI$; and luteolin hydriodide, $C_{15}H_{10}O_6.HI$. It is also shown that whereas quercetin tetramethyl ether resembles the monomethyl ether of rhamnetin in reacting with sulphuric acid, and not with the haloid acids, dibromoquercetin and tetrabromo-morin yield no compounds with mineral acids. The other known members of the quercetin series are dioxylavone (Friedländer and Rüd., Ber. 1896, 878) and chrysin, the colouring matter of poplar buds. The former has been shown by its discoverers to yield acid compounds, but, on examination, the latter was found to be devoid of this property. Various members of the ketone group (gallaacetophenone, alizarin, and maelurin), of the xanthone group (gentisin, euxanthone, datiscetin), and of the anthraquinone group, were examined in this respect, but yielded no compounds with mineral acids. Catechin and kinoin also, the latter a constituent of malabar kino, did not react.

For the constitution of the acid compounds two schemes are put forward, the first a similar one to that suggested by Nietzki and Schröber (Ber. 1895, 50) for the phthalicin salts, and a second depending upon the saturation of the ethylene bond in the *γ*-pyrone ring.

It is considered probable that this reaction is characteristic of the quercetin group, and will thus be of service for distinguishing its members from the other classes of non-nitrogenous, yellow, mordant dyestuffs which are at present known to exist.

PATENTS.

Dyestuffs [Yellow, Brown, and Black] for Cotton. The Manufacture and Production of. H. E. Newton, London. From "The Farbenfabriken vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 22,417, Nov. 23, 1895.

COTTON colouring matters have been obtained by heating sulphur and alkaline sulphides together with amidosulphonic acids or nitrosulphonic acids, amido or nitrohydroxysulphonic acids, hydroxy- or dihydroxysulphonic acids of the benzene or naphthalene series. In the present specification these sulphonic acids may be replaced by carboxylic acid derivatives or by the simple hydroxy derivatives of the benzene or naphthalene series, such as phenol, the cresols, xylenols, resorcinol, its isomers and homologues, *α*- and *β*-naphthol, dihydroxynaphthalene, and the like. The colouring matters dye unmordanted cotton from yellow, through brown and olive-green, to greyish-black and deep black, not only from hot but also from cold baths, and give shades fast to light, alkalis, acids, washing, and fulling. For example, a mixture of 1 kilo. of nitrosalicylic acid, 2 kilos. of sulphur, and 6 kilos. of sodium sulphide ($Na_2S + 9H_2O$) is heated in an oil-bath to 160° C., with constant agitation. The melt at first froths violently, and when this has subsided, the temperature is slowly raised to about 250° C., which is maintained for about 3—4 hours. When cold, the melt is dissolved, together with 3 kilos. of sodium sulphide, in hot water, filtered, and evaporated to dryness. The greenish-black mass produced, can be employed directly for dyeing, and cotton kept for several hours in a cold aqueous solution of it becomes dyed a greenish-black. An analogous method may be employed for obtaining a dyestuff from crude cresol. A mixture of

1 kilo. of crude cresol, 1 kilo. of sulphur, and 1.4 kilos. of caustic soda-lye (sp. gr. 1.355) is heated under an inverted condenser on a water-bath until the melt has become uniform. It is then heated in an oil-bath for 4 hours to 170° C., and for a further 4 hours to 250° C. (temperature of the oil in each case). The melt may then be used directly for dyeing, and it gives in a cold bath, together with a little sodium sulphide, dark brown or brownish-black shades on unmordanted cotton fast to alkalis, acids, washing, and light. Instead of using the melt directly, it may be dissolved in 10 litres of water, filtered, and the dyestuff salted out. On drying, it then forms a greyish-black powder, which dissolves easily in water and turns blue on the addition of an alkaline sulphide. One kilo. of β -naphthol is heated on the water-bath under a reflux condenser, with 2 kilos. of sulphur and 5 kilos. of sodium sulphide until a uniform melt is obtained. The temperature is then raised by means of an oil-bath, first to 160° C. and afterwards to 200° C., where it is maintained for 2–3 hours with constant agitation. When cold, the melt is dissolved in hot water, filtered, and evaporated to dryness. The brownish-black mass obtained may be readily powdered, and dyes unmordanted cotton brown from a hot bath containing soap and potassium carbonate, and a deep brown-black from a cold bath in presence of an alkaline sulphide. Under similar treatment, α -naphthol gives a greyish-black and 2,3'- or 2,2'-dihydroxynaphthalene give dark-black colouring matters.—T. A. L.

Basic Blue Dyestuffs, Manufacture of. O. Imray, London. From "The Farbwerke vormals Meister, Lucius, and Brüning," Höchst a. M., Germany. Eng. Pat. 23,853, Dec. 12, 1895.

THE process consists in heating together under pressure in an indifferent solvent, a safranin together with an aromatic diamine. The most valuable colouring matters thus obtained have been those produced from a safranin containing an alkylated nitrogen and diamidodiphenylmethane, diamidodiphenylmethane, diamidodiphenylmethane, and *p*- and *m*-phenylenediamine. An autoclave, provided with an agitator, is charged with 50 kilos. of dimethylsafranin (from dimethyl-*p*-phenylenediamine and aniline), 25 kilos. of diamidodiphenylmethane, and 250 litres of water, and heated for 4–6 hours at 180° C. until the reddish-violet safranin colour has disappeared. More water and the necessary quantity of hydrochloric acid are then added, when the whole melt dissolves up. The dyestuff may be precipitated with salt and zinc chloride, when it forms a black sandy powder, which dissolves easily in water with a blue colour. Sodium carbonate or acetate precipitate the violet-red base, and sulphuric or hydrochloric acid also precipitate the dyestuff. The solution in concentrated sulphuric acid is green, which turns blue on dilution with water. By heating in the same manner as above 50 kilos. of dimethylsafranin with 300 litres of an aqueous solution containing 25 kilos. of *p*-phenylenediamine, a similar colouring matter is obtained, which, however, gives a pure blue, and not a reddish-violet, when its solution is precipitated with alkalis. The condensation can also take place in alcoholic solution, the alcohol being distilled off previous to the separation of the dyestuff.—T. A. L.

Colouring Matters [Cotton Yellow], Impts. in the Manufacture of. H. H. Lake, London. From K. Ochler, Offenbach-on-the-Maine, Germany. Eng. Pat. 1331, Jan. 18, 1896.

THIS colouring matter, which dyes unmordanted cotton yellow, is a derivative of tolylene diamine sulphonic acid [$\text{CH}_3 : \text{NH}_2 : \text{SO}_2\text{H} : \text{NH}_2 = 1 : 2 : 4 : 6$] and nitro-*m*-phenylenediamine, and is obtained according to the following process. A solution containing 11.2 kilos. of the sodium salt of the above-mentioned tolylene diamine sulphonic acid together with 6.9 kilos. of sodium nitrite in 500 litres of cold water is poured into an ice-cold dilute solution containing 50 kilos. of hydrochloric acid of 22.5° B. When the nitrite has all been taken up, the liquor is poured into a solution of 15.5 kilos. of nitro-*m*-phenylene diamine "in the calculated quantity of strong diluted muriatic acid," when an orange precipitate is at once formed. After

standing 24 hours, the whole is heated to boiling and the dyestuff acid is converted into its sodium salt by the addition of 35 kilos. of sodium carbonate, after which it is salted out and dried. It forms a light brown powder, soluble in water to a yellow solution, which gives a gelatinous yellowish precipitate on the addition of an acid. The colouring matter gives clear yellow shades on unmordanted cotton, whilst by employing an acetic acid solution in the above process very much paler shades can be obtained.

—T. A. L.

Colouring Matters of the Rhodamine and Rhodol Groups, Manufacture of. O. Imray, London. From "The Society of Chemical Industry in Basle," Basle, Switzerland. Eng. Pat. 19,516, Sept. 3, 1896.

IN the preparation of rhodamine sulphonic acids it is the *o*-tolyl derivatives which are the most valuable. Hitherto it has been impossible to obtain a remunerative yield of a sufficiently pure product. The patentees have discovered a method of separating a phthalic derivative of *m*-oxyphenyl-*o*-tolylamine which can be applied for the preparation of a whole series of *o*-tolylrhodamines. When *m*-oxyphenyl-*o*-tolylamine is heated with phthalic anhydride it is observed that the melt, which at first is fluid, thickens towards 120°–130° C. If, when this takes place, the melt be cooled and extracted with alcohol, the residue consists of the condensation product (consisting of equivalent quantities of phthalic anhydride and *m*-oxyphenyl-*o*-tolylamine), which forms minute greenish-yellow tablets. The new compound is sparingly soluble in ordinary organic solvents and is insoluble in dilute mineral acids, but dissolves easily in alkalis. It turns violet when heated to 180° C. and melts above 200° C. with complete decomposition. On fusing with resorcinol or other products employed in the production of rhodamines, reaction readily takes place, forming *o*-tolylrhodol and *o*-tolylrhodamine. These products can be very readily sulphated by heating with 80 per cent. sulphuric acid on the water-bath, and yield rhodamines soluble in water, which dye wool and silk evenly from an acid bath violet-red to reddish-violet shades fast to air and light. The following examples give the quantities employed. A mixture of 17.5 kilos. of the condensation product, 5.5 kilos. of resorcinol, and 15 kilos. of potassium bisulphate, is heated with constant agitation to 170°–175° C. for about one hour until the melt thickens. On cooling, it forms a brittle vitreous mass, which, after pulverisation, is extracted first with water and afterwards with toluene. The resultant residue when ground forms a brown powder and consists of the sulphate of *o*-tolylrhodol. (According to Ger. Pat. 54,684 "rhodol" is the simplest rhodamine in which an amido group has been replaced by hydroxyl.) In a similar manner the sulphate of *o*-tolylhomorhodamine is obtained by heating together 17.5 kilos. of the condensation product, 6.2 kilos. of *o*-amido-*p*-cresol—

and 15 kilos. of potassium bisulphate to 190° C. until a fluid melt is obtained, when it is allowed to fall to 180°–183° C. and kept at this temperature for one hour, being subsequently worked up as above. The sulphonation is carried out as follows:—1 kilo. of *o*-tolylrhodol sulphate is dissolved in 5 kilos. of sulphuric acid (66° B.), and heated to 45°–50° C. until a sample is completely soluble in sodium carbonate solution. The melt is then run into 90 litres of water and the sulphonic acid filtered off. After washing, to remove the greater part of the sulphuric acid, it is dissolved in sodium carbonate solution, and the sodium salt of *o*-tolylrhodol sulphonic acid is salted out. The brilliant brown powder obtained is readily soluble in water, and dyes wool and silk reddish-violet from an acid bath. In a similar manner dimethyl-*o*-tolylrhodamine sulphate (from dimethyl-*m*-amidophenol and the condensation product) is converted into a sulphonic acid by heating with 10 times its weight of 80 per cent. sulphuric acid for 4–5 hours on the water-bath. The sulphonation can also be effected by means of fuming sulphuric acid, but in this case at a temperature of 0–5° C. A table is appended to the specification giving reactions of the various rhodols and rhodamines obtained by the methods described.—T. A. L.

V.—TEXTILES: COTTON, WOOL, SILK, Etc.

Cotton, A New Process for the Production of Silk-like Gloss on. II. Lange. *Färber Zeit.* 7, 441—442.

In the well-known mercerising process, the cotton contracts by about 17 per cent. of its original length, and after the treatment with caustic soda and washing with water, it is not possible by stretching to restore the fibre to its former length. According, however, to a patent of Messrs. Thomas and Prevost, of Crefeld, if the cotton be kept in a stretched condition during the mercerising process, or if it be stretched after the treatment with caustic soda and before washing, the yarn or fabric may not only be caused to retain its original length, but the cotton acquires at the same time a lustrous appearance similar to that of *chappe silk*. Cotton thus treated is inferior in tenacity to mercerised but superior to unmercerised cotton, and in power of attraction for colouring matters it also occupies an intermediate place. When examined microscopically, the fibres appear round and perfectly transparent.—R. B. B.

Waterproofing of Fabrics, Fibres, and Paper by means of Formaldehyde. *Leipziger Färber u. Zeugdrucker Zeit.* 45, 484.

ACCORDING to Ger. Pat. 88,114, Sept. 24, 1893, *Chemische Fabrik auf Actien* vormals E. Schering, Berlin, textile fabrics or paper, &c., are saturated with gum or gelatin solution, and then subjected to the action of gaseous or dissolved formaldehyde. The gelatin becomes insoluble in hot water and forms an impervious elastic coating. Substitutes for gutta-percha paper for antiseptic bandages may thus be prepared.—R. B. B.

New Process of Retting Flax and Hemp. U.S. Cons. Reps., Oct. 1896, 295.

AT a meeting of the Flax Supply Association of Belfast, held on July 29 last, a paper on an improved system of retting flax and hemp, the invention of Messrs. Loppens and De Swarte, was read, in which it was claimed that by a simple arrangement of apparatus, the virtues of the system of steeping flax in the River Lys, which had hitherto been supposed to belong to that river alone, could be extended indefinitely. Any water free from a mixture of lime or iron could be made as efficient as the waters of the Lys.

The new process has been at work two years, and flax retted thereby has been regularly sold in the market of Courtrai, Belgium.

The following is an abstract of the system:—

It appears that the retting tanks are made up of two principal parts, the upper and the lower, separated from each other by an open floor. On the walls of the upper part, means are provided for keeping the flax straw suitably submerged by crossbeams, working in vertical slides, and capable of being fixed at any required height. In the lower part of the tank the inlet is provided just under the open floor, and the outlet at the floor proper. The flax straw is tied up in double sheaves, the root end of one half being placed alongside the top end of the other, and so approximately cylindrical in shape; these sheaves are placed in a vertical position on the open floor, moderately tight, and as regularly as possible; ordinary straw is then spread over the top to keep off dust or the effects of the weather, and boards are placed on this to equalise the pressure of the crossbeams, which are fixed so as to insure the straw being suitably submerged when the tank is full and working. The tank is then filled by opening the inlet and closing the outlet, and, as the level of the water rises, the straw rises also, till it is stopped by the crossbeams, where it remains motionless, pressing upwards all the time more or less. The inlet and outlet taps are then regulated so as to maintain the water at the right level and insure its being often enough changed. The changes which occur in the retting mass may be set down as follows:—The water surrounding the stalks dissolves various vegetable substances, some of which are naturally soluble, while others become so under the action of fermenta-

tion. Thin streamlets of heavy juices are thus formed which flow down the stalks and slowly cross the layer of fresh water below the retting mass, and this without mixing with it, owing to the extreme slowness of the motion; on the bottom of the tank they then form a layer of dirty and denser water, which runs off by the outlet, while, at the same time, the fresh water just above it works its way up through the retting straw, also in the form of thin streamlets, which take the place of the descending ones. This circulation, consisting in the natural fall of heavy juices and the corresponding rise of fresh water, takes place uniformly and to the exclusion of every other with equal facility in every part of the retting mass, owing to the vertical position of the stocks and the equal pressure all over the tank. The principal advantages which may be expected to be derived from the system are the following:—(1) The possibility of natural retting in running water—that is to say, the best; (2) the greatest uniformity obtainable in retting; (3) larger yield of fibre than any other system; (4) the results are certain and invariable; (5) it saves labour; (6) it limits the water consumption to what is strictly necessary to natural fermentation; (7) full benefit is derived from the water used in retting; (8) rivers are not contaminated; and (9) it is suitable for every part of the world where flax or hemp is cultivated.

The association considered this method of steeping flax so important that a committee was appointed to confer with the patentees and ascertain from them on what terms they would be prepared to grant a license for the use of their patent in Ireland, and report to a joint committee appointed by the Irish Land Commission for the improvement of the culture of flax.

Weighting in Silk Yarn, The Quantitative Estimation of. Herzfeld. *Leipziger Färber u. Zeugdrucker Zeit.* 45, 485.

See under XXIII., page 923.

PATENT.

Cotton Waste or other Fibrous or Textile Material, Impts. in Cleaning or Removing Grease from, and in Apparatus therefor, and for Recovering the Solvents. J. W. Mitchell, Rawtenstall. Eng. Pat. 23,429, Dec. 6, 1895.

THIS invention relates to the bleaching and scouring of cotton waste that has been used for the cleaning of machinery, the oil being removed by means of volatile solvents such as "benzene," both oil and solvent being recovered.

The apparatus consists of a kier A, mounted upon trunnions B, upon which it is caused to rotate by suitable gearing, such as the spur wheel C on one trunnion, and the pinion *c* driven from the pulleys D by the bevel wheels *d*, worm (not shown), and worm wheel E. Through each of the trunnions B is passed a pipe F and G respectively, terminating inside the kier, one at the top and the other at the bottom, in pipes *f* and *g*. To the tube F are connected three branch pipes, of which L leads to the still M, K to the reservoir containing "any suitable scouring liquor," and H (not shown) serves as a supply of steam. The tube G at the other trunnion is connected by means of the pipe N with the condenser O. Each of these pipes is provided with suitable valves or stop cocks. The still M is connected with the condenser P, and the condensers are respectively connected with the tanks R and S (of which the latter only is shown) by the pipes *o* and *p*.

The still M, which is heated "by a steam coil or other suitable means," and the condenser P are so arranged that a continuous circulation of the "benzene" or other solvent can be carried on through the kier A, being pumped in through the tube G, and back through the still M, and condenser P, to the store tank R (on the other side of S, and not shown), from which it is again pumped into the kier.

The operation is as follows:—The greasy waste is put into the kier A, which is then caused to rotate slowly. The solvent is pumped into the kier through pipe G, until it overflows through pipe L, into the still M, until the solvent

runs off nearly clear. The solvent is recovered from the oil in the still M by distillation, the vapours being passed through condenser P, and thence through the pipe p to the

tank R (not visible). Steam is then admitted into the kier to vaporise the solvent remaining in the material, the vapours being passed through the condenser O to the storage tank S.

"A suitable lye or scouring liquor" is then pumped into the kier through branch pipe K, and "the material boiled until the operation is completed."—1. S.

VI.—DYEING, CALICO PRINTING, PAPER-STAINING, AND BLEACHING.

Leather, The Dyeing of, for Shoes. H. Burgess. J. Soc. Dyers and Colourists, 1896, 12, 207.

Brown shoe leather, for which a largely increased demand has been evident for the last few years, is manufactured principally from calf skin for the better article, and from sheep skin for the inferior. Sheep skins are largely imported from Australia and New Zealand, already tanned, the tanning agent being the bark of the various species of acacia, natives of Australia, which contain the deep red mimotannic acid, and consequently the tannage is of a reddish-tint; these skins are capable of being beautifully dyed.

In preparing tanned calf skins for dyeing, the large quantity of ellagic acid ("bloom"), which is almost invariably precipitated during the tanning process, and which becomes intimately mixed with the fibres of the skin, must be removed, or very poor shades will result. The goods are first shaved down to the required substance, and are then agitated with warm water in a revolving drum to break and soften them, this operation also removing a portion of the "bloom." The skins are then placed on a marble slab, and each one knocked out perfectly flat and level, the grain of the skin being smoothed out until it presents an even surface. The grain of the skin is then scoured with a kind of brass brush, and the

"smoothing-out" process repeated, thus removing the remainder of the "bloom" from the skin. The skins are then treated with a very weak, warm solution of soda crystals to remove surface grease, then with sulphuric acid of about 0.75 per cent. strength, and finally with water until they no longer taste acid, or, if to be dyed with acid colouring matters, only slightly so. After draining, the skins are smoothed out on the grain side, and are then placed flesh side together in pairs, ready for the dye-bath.

Owing to the great difference in weight of similar-sized skins, and to the fact that only the grain side of the skin must necessarily be dyed, it is impossible to calculate percentages of colouring matter simply to weight of skins; the correct proportions are only to be learnt by experience. The acid colouring matters are so easily applied to leather, and the results are so satisfactory, that they are to a large extent replacing other classes of colouring matters. The goods are entered into the bath at the maximum temperature (about 112° F.), and the bath allowed to cool slowly. The goods are turned over by hand in the dye bath, care being taken that no single pair shall remain long at the bottom of the pile. To effect a saving of labour, the skins may be dyed in large paddles or reels, but a certain amount of colouring matter is wasted by being absorbed on the flesh side of the skins; also the variety of shades obtained is greater, skin for skin, than when the first method is used.

With the following three colours, *viz.*, Azo Flavin R S, Fast Brown, and Blue Black (Induline), almost any shade of brown required for shoe purposes may be obtained.

Eight parts of Azo Flavin and 0.5 part of Fast Brown produced a light Russia brown shade.

Four parts of Azo Flavin, 1 part of Fast Brown, and 0.5 part of Blue-Black produce a medium shade of brown.

Four parts of Azo Flavin and 2 parts of Fast Brown produce a red-brown.

To produce a chocolate or dark brown, 1 part of Blue-Black and 1 part of Fast Brown are first applied to the skins; afterwards to the same bath is added a mixture of 4 parts of Azo Flavin and 1 part of Fast Brown.—A. S.

Cotton, Bleaching of, by means of Electrolytically prepared Solutions. H. Wartner. *Leipziger Färber u. Zeugdrucker Zeit.* 45, 449—451.

MEETING with considerable difficulties in the industrial application of the electric bleaching process, A. Vogelsang, of Dresden, has recently devised improved apparatus with which he is said to have achieved perfectly satisfactory results.

The cotton yarn should be closely packed in very concentrated liquors prepared in a vessel (the electrolyser) through which flows a solution of rock salt, while at the same time an electric current from a dynamo machine circulates through the liquid. The bleaching liquid obtained in this manner is kept in closed vessels until required for use. The advantages of the electric bleach are thorough and even bleaching, and, compared with the use of bleaching powder, less liability to tender the cotton, and decreased cost. Although the initial expenditure is somewhat great, the cost of working is low, and at present prices a bleacher could recoup himself in two years for his original outlay. The cost of the necessary plant, exclusive of buildings, is about 425*l.*, made up as follows:—Electrolyser, 180*l.*; vessels for boiling and bleaching, each to hold 1,500 lb., complete with pump, 75*l.*; dynamo machine, which can also be used for electric lighting purposes, 45*l.*; squeezing rollers or hydro-extractor, 30*l.*; washing machine, 75*l.*; various wooden casks, 20*l.*. Two men can bleach and wash off 1,500 lb. of yarn in a day.

It is important to note that a water supply which is unsuitable for bleaching by the ordinary method is equally so for the purpose of electric bleaching.—R. B. B.

Chappe Silk, A New Process for the Softening and Bleaching of. A. Eichholzer. *Leipziger Färber u. Zeugdrucker Zeit.* 45, 483—484.

"CHAPPE silk" is the product of bored and double cocoons, as well as of those injured in steaming, also the inner and outermost portions of the cocoons. It finds extended use in the manufacture of plush and velvet, and its chief requirements are softness and a thorough bleach, in order that pure and bright colours may be obtained.

Softening.—If the acid remaining in the fibre from dyeing be not perfectly neutralised, the iron and steel parts of the looms are attacked, and, to avoid this, dyeing usually takes place in a very weak acid bath with the addition of chappe "boiled-off" liquor. After dyeing, the silk is worked in two or three successive baths of cold water and then softened in a bath containing per kilo. of silk, 20 grms. of alum and 10 grms. of soda. In this process there is a great waste of dye-stuff on account of the insufficient acidity of the dye-bath. According to the new process the chappe is dyed in a "broken" soap-bath, as usually employed with acid colours for silk, and after one or two baths of cold water it is softened with a mixture consisting of 2 litres of olive oil, 1 litre of sulphuric acid of 66° B., and 1 litre of alcohol. Of this mixture 150 c.c. are used per kilo. of silk, the yarn is given seven turns and then hydro-extracted.

Bleaching.—Until recently, "chappe" was bleached with hydrogen peroxide and silicate of soda. Sodium peroxide is, however, to be preferred, and the process may be carried out as follows:—After boiling-off in the usual manner and washing out the soap, the silk is entered into a bath prepared by gradually dissolving 3 kilos. of sodium peroxide in 25—30 litres of cold water and pouring the solution into water at 55° C. In this bath the silk is turned three times, the temperature is then raised to the boil, and after working half an hour in the cooling bath, the temperature is again raised to the boil. After another half hour the silk is taken out, given three turns in water at 30° C., and

worked a quarter of an hour in a bath containing 30 per cent. of Marseilles soap. It is then hydro-extracted and is ready for dyeing.

For very pale shades the chappe may be further bleached in the sulphur chamber or with liquid sulphurous acid.

—R. B. B.

Wool-Bleaching with Bisulphite by the Wet Process.

Leipziger Färber u. Zeugdrucker Zeit. 45, 471.

THE process for 10—15 kilos. of wool in the form of loose wool, yarn, or piece goods is as follows:—The wool is well washed and hydro-extracted, then worked in a bath containing 500 litres of cold water free from iron, 4 litres of sodium bisulphite 38°—40° B., and 300 c.c. of sulphuric acid 66° B. After 25—30 mins. it is taken out, allowed to drain, and then tinted in a fresh bath with Alkali Violet or Methyl Blue. Finally, it is rinsed and dried at the ordinary temperature, or, if the presence of bisulphite be unobjectionable in the operations which follow, rinsing may be omitted.

The bleaching bath may be used for several successive lots of material, if for each fresh lot four-fifths of the original amounts of bisulphite and sulphuric acid are added.

—R. B. B.

Coloured Woollen and White Half-Wool Goods, Acid Stains on. *Leipziger Färber u. Zeugdrucker Zeit.* 45, 468—469.

DARK stains on dyed woollen pieces are a well-known source of trouble to the dyer, and a frequent cause of this defect is imperfect neutralisation after the carbonising process. If goods from which the acid has not been entirely removed are imperfectly hydro-extracted, or if the pieces remain hanging over frames, &c., the acid collects in patches and causes dark stains when dyeing in a neutral or alkaline bath, e.g., with Indigo or Alkali blue.

Similar stains occasionally occur in pieces which have not been carbonised, and may arise from want of perfect cleanliness, e.g., a piece may be washed or hydro-extracted in a washing machine or hydro-extractor in which a piece containing acid has been previously treated.

In the case of white half-wool flannels dirty-yellow stains may be caused, and the cotton may even be tendered and holes made in the fabric by the oxidation of the sulphurous acid on the material during bleaching to sulphuric acid, owing to the admittance of air into the sulphur chamber. The sulphuric acid can be prevented from spreading and its injurious action confined to the parts originally attacked by steeping the goods in water after bleaching, and such treatment is also useful in removing the odour of SO₂. It is possible that the purity of the white may be affected by this treatment with water, but the pure white is easily restored by tinting with Methyl Violet.—R. B. B.

Alizarin Blue S, in Paste and Powder, and its Application in Calico and Linen Printing. *Leipziger Färber u. Zeugdrucker Zeit.* 45, 459.

THE application of Alizarin Blue S in printing depends upon its decomposition during steaming into its constituent parts, viz., insoluble Alizarin Blue and sodium bisulphite. Evidently a premature decomposition of the colour before printing must be avoided, and for this reason the ingredients of the printing colour should be mixed together in the cold. This is easily carried out, since Alizarin Blue S, even in powder form, is readily soluble in cold water, or in the cold thickening. The colour should be used as soon as prepared, since it rapidly deteriorates and produces only poor and dull shades. An addition of potassium sulphocyanide is frequently made, to obviate the deleterious effect on the colour of contact with iron. The printing colour for a medium blue shade should consist of 100 grms. of Alizarin Blue S paste, 740 grms. of starch-tragacanth thickening, 10 grms. of potassium sulphocyanide, 20 grms. of calcium acetate at 20° B., and 130 grms. of water. After printing, steam for half an hour without pressure, and finish by clearing and seaping in the usual manner. The colours are said to be exceedingly fast to light, soap, and chlorine.—R. B. B.

Diazo Compounds with Zinc Chloride in Printing on Goods prepared with Sodium-Beta-Naphthol; The Application of Double Salts of. A. A. Smirnoff and B. A. Rosenthal. *Färber Zeit.* 7, 442—443.

The chief obstacle to the more extended use of "ice colours" in printing is the unstable nature of the diazo printing colour, it being necessary to prepare fresh colour three or four times daily, and this involves the expenditure of much time and labour and the use of large quantities of ice. This difficulty may be removed by substituting for the diazo compounds, their double salts with zinc chloride, for these salts mixed with cold tragacanth thickening may be preserved unchanged for several days.

The diazo solution is prepared in aluminium or enamelled iron vessels in the ordinary manner, and when diazotisation is complete the requisite amount of zinc chloride is gradually added with continual stirring. The double salt is formed as a voluminous precipitate, which, after settling, is thrown on to a filter and allowed to drain.

The goods prepared with sodium- β -naphthol (to which is added sodium acetate) are printed with a colour consisting of this paste and tragacanth thickening, then passed through a weak hydrochloric acid bath, washed, and soaped. The most satisfactory results have been obtained with α -naphthylamine hydrochloride, which yields a bright cardinal of a yellowish tone.—R. B. B.

Woollen Pieces dyed with certain Colouring Matters. Process to make Fast to Finishing Operations. [Addition of Oxidising Agent with Colour.] Leipziger Färber u. Zeugdrucker Zeit. 45, 471.

ACCORDING to a recent German patent, the colour of woollen goods dyed with certain azo dyestuffs suffers a considerable change during finishing operations where heat is employed, owing to decomposition of the colouring matter into its component parts. The blacks, for example, dyed with amido-azo naphthalene derivatives change to brown on steaming under pressure. This decomposition can be avoided by the addition of a suitable oxidising agent to the dye-bath. The oxidising agent must be one which is not reduced by the wool itself, and copper salts or chlorates are found to be the best for this purpose. An addition should be made of 3—4 per cent. of copper sulphate, or 5—8 per cent. of a chlorate (on the weight of wool); if chlorates are employed the pieces must not be washed after dyeing. Dyestuffs which are rendered fast by this process are Naphthylamine Black D, Naphthyl Blue-Black N, Anthracite Black, Jet Black, and Sulphone Black.

—R. B. B.

p-Nitraniline Red on Cotton Yarn. W. Römer. *Färber Zeit.* 7, [27], 425—426.

THE processes published by the colour manufacturers were all intended for the use of piece dyers, for which purpose they are well suited, but did not answer for dyeing in the hank. Even the special process of Ulrich (*Färber Zeit.* 5, [18], 285—287) has been found difficult of application on account of the great care that was necessary in carrying it out. The first practical process for yarns, the author says, originated in Alsace. Its main features are simplicity of manipulation and its adaptation to the machinery of the Turkey-red dyer. The process is as follows:—A lead-lined vessel of about 15 litres capacity is charged with 30 litres of water and 1 kilo. of soda-lye of 10° B., and the mixture is heated to boiling with steam, using a lead pipe for the purpose. 1,200 kilos. of β -naphthol are next added, and when this is dissolved, 4,250 kilos. of 50 per cent. Turkey-red oil. The whole is then made up to 40 litres, and allowed to cool.

The previously boiled and dried yarn is impregnated with this solution in single lots of $\frac{1}{2}$ kilo. each. This is done in precisely the same manner as the oiling in the Turkey-red process, the same machine being used for the purpose. The hooks and the pan of the machine are all lead-coated. After impregnation, the yarns are centrifugalised (the surplus liquor being returned to the stock) and dried on a Hartmann rotating drying machine at 60° C.

The developing bath is prepared as follows:—In a wooden vessel of about 12 litres capacity, 2,070 kilos. of *p*-nitraniline are made into a paste with 1,750 litres of boiling water, 3,900 kilos. of hydrochloric acid of 20° B. are next added, and then 3,25 litres of boiling water, the whole being stirred whilst these additions are being made. A clear solution is thus obtained, which is immediately allowed to run in a thin stream, preferably through a glass siphon, into 350 litres of cold water, the latter being kept stirred. A fine precipitate separates, which, on the addition of 1,080 kilo. of sodium nitrite, soon dissolves again. The nitrite solution must be added quickly and all at once, whilst stirring briskly.

$\frac{5}{8}$ litres of this solution are put into the pan of an oiling machine, along with 400 c.c. of a cold solution of sodium acetate (3 kilos. to 30 litres of water) and 3 litres of cold water. One half kilo. of yarn is immersed in this solution, and passed through the machine until the colour is developed. The surplus liquor is run into an empty vessel and preserved. A second lot of $\frac{1}{2}$ kilo. is treated in a similar way, and to the liquor now remaining in the pan is added that left from the first lot, and in this a third lot is developed, after which the liquor is considered exhausted, and run to waste. This process is continued until the whole batch is developed. The yarn is then soaped, rinsed, passed through acidulated water, rinsed again, and dried.—I. S.

PATENTS.

Coloured Border Effects, Impts. in the Production of, on Fast Black-dyed Grounds upon ordinary Grey Cotton Cloths, especially suitable for Umbrella Cloths, Selvedges, and the like. L. C. G. Sharp, Low Moor, Bradford. Eng. Pat. 21,355, Nov. 11, 1895.

THE production of white or coloured selvedges on fast black cloth, consisting essentially in printing white or coloured resists on cloth impregnated with an aniline black mixture, after drying, but before the development of the black.—I. S.

[Cotton] Bleaching, Washing, Dyeing, and Drying Yarn in the Cop, Impts. in Apparatus for. M. H. Smallwood. Manchester. Eng. Pat. 22,185, Nov. 21, 1895.

THE apparatus consists of an upright cylindrical vessel, steam jacketed, and provided with a hinged cover secured by swivel bolts. A smaller cylindrical vessel, also provided with a removable lid, is placed inside the large vessel, and in its sides are drilled and tapped rows of small holes, into each of which is screwed a perforated tube carrying the cops. To charge the apparatus, the inner vessel is raised by means of a crane, the tubes carrying the cops are screwed into the holes, and the vessel is then lowered into the outer case, which is closed by the lid.

A system of pipes and valves communicate with the inner and outer vessels, and several tanks containing bleaching, dyeing, washing, and other liquors, which are circulated through the apparatus as may be required.—I. S.

Cotton and Cotton Goods, A New or Improved Process of Bleaching. A. Ender, Dornach-Mülhausen, Alsace, Germany. Eng. Pat. 14,252, June 27, 1896.

BLEACHING cotton and cotton goods by treating them with a lye containing an alkaline chloride or similar compound, and thereafter steaming and pressing them.—I. S.

Dyeing Improved Spot, Random, or any other Particoloured Dyed Yarns. [Use of Metal Clips.] G. White, Leicester. Eng. Pat. 23,466, Dec. 7, 1895.

THE improvement consists in using metal clips to take the place of paper, string, knots, &c., hitherto used for the purpose of protecting parts of the yarn from being acted on by the dye-liquor.—I. S.

Mordants, Metallic; Impts. in Fixing on Fibres and Fabrics. A. Ashworth, Bury. Eng. Pat. 4890, March 4, 1896.

THE inventor claims the discovery of a new method of mordanting fibres, "rendering the steaming or dunging

process used with vegetable fibres unnecessary, simplifying also the mordanting of animal fibres, and producing fixed metallic mordants on the fibre." This new process requires the employment of "two metallic salts, both or one of them containing a metallic mordant, or consisting of a salt capable of conversion into a metallic mordant, selected in such a way that, if one of the salts only belong to the class of metallic mordanting agents, it must be easily decomposable and contain an acid more powerful than the one contained in the second salt, the acid of which has to be volatile; or if both be metallic mordanting agents, both must be decomposable and one of them must be combined with a more powerful acid than the other, whilst the acid combined with the latter must be volatile."

The following examples are given:—(1.) 100 parts of "bisulphite of iron," 18° Tw., and 50 parts of "muriate of chrome," 32° Tw., are mixed together, the cloth or fibre is passed through until it is saturated, dried, preferably in hot air, washed in hot water at about 90°–95° C., and dried. "The mordants will be found to be fixed without the aid of further dunging or steaming, and the fibre or fabric is ready for use." (2.) 100 parts of iron bisulphite, 18° Tw., and 100 parts of a 1 per cent. solution of sodium bichromate. (3.) 100 parts of aluminium acetate, 20° Tw., and 50 parts "muriate of iron," 20° Tw. (4.) 100 parts of aluminium chloride, 23° Tw., and 100 parts of sodium bisulphite 75° Tw. (5.) 100 parts of "muriate of chrome," 32° Tw., and 100 parts of sodium bisulphite, 75° Tw. (6.) 100 parts of a 10 per cent. solution of stannous chloride, and 100 parts of aluminium bisulphite, 26° Tw.

Some of these mordants may be used without further treatment as colours themselves.—I. S.

VII.—ACIDS, ALKALIS, AND SALTS.

Glover Tower. F. Lütj. Zeits. f. ang. Chem. 1896, 645–649.

In recent times many proposals have been made to replace the lead chambers in vitriol manufacture by reaction towers, so that the system consists of Glover and Gay-Lussac towers with the reaction towers between these. Should this proposal be carried into effect the Glover tower would become still more important than at present, and its proper construction would be a matter of still greater moment. Whilst the position of the tower, its dimensions, distance from the burners, and arrangement of the dust flue are important factors for a proper working, the inner arrangement plays still greater part than these. The function of this inner arrangement is to bring the hot gases entering below into the best possible contact with a down-flowing liquid without at the same time rendering the gas current too slow. Whilst a flint packing, as formerly used, only leaves some 15 per cent. of the tower space for the entering gases, the regular stone blocks allowed 35 per cent. of this space to be used, and with a properly-arranged cylinder-filling, this value can readily be increased to 58 per cent. This large capacity for gas is not, however, alone sufficient to ensure satisfactory working; it is still more necessary to bring the gas into intimate contact with large surfaces of the down flowing acid. On account of the tendency of the gas to travel upwards in a perpendicular direction, horizontal contact surfaces are to be avoided, and therefore the horizontally disposed stones before mentioned are not the most advantageous form of filling. The author also considers it open to question whether the recently introduced distributing cones are really efficient, since they both diminish the draught and have much useless surface.

With cylinders it is possible, by making use of the exterior and interior surfaces, to divide up a liquid very completely, and at the same time to offer continually fresh acid surfaces to the rising gases. It is essential that the cylinders should have a rough surface to hold the acid as much as possible during its descent, and also that they should be properly arranged in the tower. The author has employed, since 1885, cylinders of 160 mm. diameter, 120 mm. high, and having a wall thickness of 20 mm.

These are arranged as shown in the figure, so that each cylinder stands over the junction of three others standing in the row below.

There is thus above and below each cylinder four small passages, which are just sufficiently large to prevent frothing in the tower. About eight tiers of these cylinders give a height of one metre, and the gas must, therefore, in each metre traversed, divide and recombine itself eight times, the gas leaving each cylinder splitting up into four currents, which further on reunite. The acid passing downwards trickles partially down the sides of the cylinder and also partially falls in drops from tier to tier. Experience shows that rough-surfaced cylinders will take up more than ten times the amount of acid held by cylinders having glazed walls.

The cylinders described are white in colour and show a white stony fracture; they are harder than glass and capable of withstanding moisture, temperature change, a high temperature, and the long-continued action of various acids. They consist essentially of silica and clay burnt at a very high temperature.

The towers should not be left standing idle and open to the atmosphere, since a cylinder once used will disintegrate after a few weeks' exposure to the air, although the same cylinder will last for many years in a tower continually worked. This disintegrating action seems to be entirely mechanical, since no aluminium sulphate was found in the destroyed cylinder.

The author gives the following description of the method now adopted for packing a Glover tower:—Only moulding stones of highly acid-proof material are used; the figures apply to a round tower of 3 m. diameter. The floor is formed of a double layer of acid-proof plates 200 × 200 × 70 mm. in size, and the side walls are lined as far as the lower edge of the grid with large curved stones, 360 mm. long, resting on lead. This leaves an inner space of 2.280 m. diameter. The inlet piece for the acid-proof gas main is built into this lining and is formed by four large stones of the same thickness as the lining. The packing of the tower is borne by a grating of acid-proof plates resting on columns, which also serve to divide the gas. These columns are 1,400 mm. high and 200 × 200 mm. in section, and the plates resting on these, and supported also by the sides, are 500 mm. high and 120 mm. thick. Square stones are arranged between the columns and the sides to prevent slipping. The interspaces between the plates is 160 mm. across. On these plates are two layers of stones 340 × 80 × 200 mm., and these are followed by two layers of 250 × 125 × 60, all being arranged to form a grid. The whole is made fast by circumferential stones 250 mm., built in dry, and in a tower 10 m. high these stones are continued for some 3.5 m. above the grating, thus giving a total height of 6.25 m. From here to the top the walls are only 140 mm. thick. From the grating to the gas exit the tower is filled with the cylinders, arranged as already described. Such a tower can take large quantities of gas, will denitrate and concentrate very efficiently, and with careful treatment last a considerable period.—J. T. C.

Tetrachromite of Barium: A New Combination of Chromium Sesquioxide. M. E. Dufau. Bull. Soc. Chim. (3), 15, 1137.

This work was carried out in M. Moissan's laboratory.

The chromites of the formula MOCr_2O_3 , prepared by dry methods, are the most numerous and the better known. They are known as neutral chromites. M. Viard has formed basic chromites, whilst the author has now completed the series by forming an acid chromite of the constitution $4\text{Cr}_2\text{O}_3 \cdot \text{H}_2\text{O}$.

The author used one of Moissan's electric furnaces, lined sufficiently thickly with baryta, and charged with an intimate mixture of chromium sesquioxide and of anhydrous barium oxide in equal proportions. An arc produced by a current of 300 amperes at 50 volts pressure, was then passed over the mixture for 10 minutes. On cooling, he found a melted green mass, having a crystalline fracture. On treating this with hydrochloric acid, rapid action occurred, with liberation of much chlorine gas, and change of colour of the liquid from brown to green. He isolated and purified this crystalline portion, by repeated treatment with boiling hydrochloric acid, until nothing more was dissolved. There remained a mixture of crystals, separable into two layers by agitation in the liquid used for washing them—the lower one, dark and brilliant, representing the tetrachromite, and the upper one composed of lamellar green crystals of chromic acid.

The chromite of barium obtained in this way as small black brilliant crystals, yielded a brown powder with a slight greenish tinge. Their density was 5.4 at 15° C.

The author found this new chromite to be unattacked by hydrofluoric, hydrochloric, nitric, or sulphuric acids. Chlorine and bromine attacked it very slowly at a bright red heat, forming barium chloride and bromide respectively. Iodine had no reaction under similar conditions. Oxygen, below a red heat, produced a rapid incandescence with formation of chromate of barium; the oxygen of the air sufficed to produce this change slowly, if the chromite were powdered before heating. This great tendency to oxidise, explained the presence of the chromate in the mass found in the furnace, and also the changes which occurred on boiling the fused mass with hydrochloric acid. Steam at a red heat had no action upon the crystals; sulphur was equally inactive at a temperature which softened glass. Anhydrous hydrochloric and hydrofluoric acids acted very slowly at a red heat, and yielded amorphous fluoride and chloride of barium. The chromic oxide remained unattacked. The chromite was easily attacked by chlorate or nitrate of potash on fusion; the alkalis, both caustic and carbonate, acted similarly.

The author notes that, whilst barium yields a polychromite or acid chromite, calcium, under exactly similar conditions, yields a neutral chromite, and strontium yields no chromite, but only a chromate.—J. B. C. K.

PATENTS.

Electrolysis, A Process and Apparatus for Effecting. [Liquid Electrodes.] F. W. Golby, London. From O. Arlt, Goerlitz, Germany. Eng. Pat. 15,129, July 8, 1896.

See under XI. A., page 908.

Electrolytic Decomposition of Liquids, Impts. in or connected with Apparatus for. [Mercury Cathodes.] G. Bell and G. W. Bell, Liverpool. Eng. Pat. 20,542, Oct. 31, 1895.

See under XI. A., page 908.

Alkaline Cyanides, Ferrocyanides, and their Derivatives: Impts. in the Manufacture of [through Medium of Boron Nitride]. G. C. Downing, London. From J. R. Moise, Paris. Eng. Pat. 19,201, Oct. 12, 1895.

ANHYDROUS borax is heated with ammonium chloride to obtain boron nitride, any ammonium chloride volatilised, being condensed. The mixture of boron nitride and sodium chloride obtained is washed with hot water, acidulated with hydrochloric acid, and the boron nitride separated is heated with stated proportions of potassium carbonate and carbon, to produce a mixture of potassium cyanide and borate, according to the equation—

The cyanide is dissolved out by alcohol. When it is desired to obtain a ferrocyanide, iron filings are added to

the materials treated, and the salts are separated by crystallising out the ferrocyanide from an aqueous solution of the mixture.—E. S.

Sulphuric Acid, The Concentration of [Utilisation of Heat], Impts. in or connected with. R. England, London. Eng. Pat. 22,715, Nov. 27, 1895.

CONCENTRATED and still hot sulphuric acid is cooled by means of cold dilute (chamber) acid, which latter is thus warmed before passing to the concentrating vessels. Also, the steam and acid vapour given off from the concentrators, is passed through coils immersed in tanks, into which cold acid is run, such acid being thus partially heated preparatory to concentration.—E. S.

Alkaline Phosphates and Caustic Alkali, Impts. in or connected with the Manufacture of. [Electrolytic Method.] W. P. Thompson, London. From The Chemische Werke, formerly H. and E. Albert, Biebrich-on-Rhine, Germany. Eng. Pat. 23,572, Dec. 9, 1895.

CONCENTRATED solutions of phosphoric acid and of a soluble alkali salt, such as sodium nitrate, chloride, or sulphate, separated by a suitable diaphragm in an electrolytic cell, are electrolysed to obtain, in the anode compartment, nitric or sulphuric acid or chlorine, as the case may be; and in the cathode compartment, either a mono-, di-, or trisodium orthophosphate. The process may be interrupted at the proper time to obtain any one of these salts. A carbon anode and a lead cathode are preferably employed. When nitric acid or chlorine is produced, it may be recovered by heating the solution.

To obtain a caustic alkali, the sodium or potassium phosphate, obtained as described, is treated with caustic lime, calcium phosphate being produced as a by-product.—E. S.

Obtaining Hydrosulphide of Sodium, or Sulphate of Sodium, and Sulphuretted Hydrogen and Sulphate of Calcium from Sulphide of Calcium or Soda Residues, and Monosodium Sulphate or Bisulphate of Soda; A Process for. B. Willcox, London. From The Chemische Fabrik Griesheim, Frankfurt-on-the-Main, Germany. Eng. Pat. 720, Jan 10, 1896.

ALKALI waste is stirred in a large closed iron chamber with a little water, and then with a concentrated solution of acid sodium sulphate, which is gradually added. The reaction that takes place and the proportions to be used are indicated by the following equation:—

The lye, when separated from the calcium sulphate formed, may be used directly, or evaporated without access of air to obtain solid sodium hydrosulphide; or it may be converted into sodium sulphide by known methods. When it is desired to extract all the sulphur of the calcium sulphide, the proportion of bisulphate used is doubled, thus:—

the products being calcium sulphate, sodium sulphate, and hydrogen sulphide. The "bisulphate" used, is preferably that occurring as a by-product in certain chemical manufactures.—E. S.

Concentrating and Evaporating Liquids, Impts. in the Method of and Apparatus for, applicable also for obtaining Solutions of Salts and the like. [Circulation under Diminished Pressure.] A. Kumpmiller, Höcklingen, Westphalia; E. Schüttgen, Ischrohn, Westphalia. Eng. Pat. 17,488, Aug. 7, 1896.

THE liquid to be concentrated or evaporated is circulated through an upper vessel, called an evaporator, a vertical pipe leading from the bottom thereof to a coil in a heating vessel (through which steam or other heating medium passes), and thence through another vertical pipe back to

the first vessel, from which the vapour given off is withdrawn by means of a vacuum. If crystals separate out, there is introduced into the pipe leading from the evaporator a vessel containing a sieve upon which the crystals collect. If it is desired to dissolve salts or lixiviate ashes, they are placed on the sieve of another similar vessel, arranged on the second vertical pipe—that leading from the heater up to the evaporator. Fresh liquid may be introduced by a branch pipe into the first vertical pipe just beneath the collector for crystals, and this liquid may be the water of condensation from a condenser connected to the evaporator. —R. S.

VIII.—GLASS, POTTERY, ENAMELS.

Glass Substitutes in Germany. J. Soc. Arts, 1896, **44**, 858.

The principal substitutes for glass, in use in Germany, are tectorium, *fenster-pappe* and *hornglas*. Tectorium is a sheet of tough, insoluble gum—said to be bichromated gelatin—about one-sixteenth of an inch in thickness, overlying on both sides a network of galvanised iron or steel wire, the meshes of which are generally about one-eighth of an inch square. The tectorium in ordinary use is stated to be apparently covered on both sides with a varnish of boiled linseed oil. It is lighter than glass of equal thickness, is tough, pliant, and practically indestructible by exposure to rain, wind, hail, or any shock or blow which does not pierce or break the wire netting. It may be bent in any desired form and fastened in position by crimping, nailing, or with putty, like ordinary glass, and when punctured may easily be repaired. Its translucence is about the same as that of opal glass, its colour a greenish amber-yellow, which fades gradually to white from exposure to the sun. It is well adapted for use for illuminated windows, signs, and transparencies. For ordinary hotbeds and forcing houses, another and cheaper substitute for glass is the so-called *fenster-pappe*, which is, however, less durable than tectorium. It is prepared in the following manner:—Light wooden frames are covered with a tough, strong manila paper, fastened by nailing at the edges. The paper is then painted with ordinary boiled linseed oil until it is so saturated, that the last coat of oil forms a smooth glistening surface, like varnish. As soon as it is dry, the frame is ready for use. It admits sufficient light for growing plants, does not require to be shaded in hot sunshine, is light, durable, secure against breakage by hail or ordinary accident, and is stated to be about 100 times cheaper than glass. *Hornglas*, which has been recently patented in Germany, resembles tectorium in appearance, but is thinner and consequently lighter in weight, and the insoluble gelatin with which the wire gauze is covered is whiter and more nearly transparent than tectorium, although it may be coloured any tint that may be desired for special purposes. It is manufactured in two qualities, one being of heavier wire and with larger meshes than the other, and it is sold wholesale for a little over 5d per sq. ft. The special advantage claimed for *hornglas* is that it does not soften under sun heat. Its uses and general characteristics are similar to those of tectorium. —A. S.

PATENT.

Glass, An Improved Manufacture of. From Soc. Anonyme Belge pour la Fabrication des Émaux Artistiques. Eng. Pat. 21,286, Dec. 18, 1895.

For producing a plate of the new material a mould of cast iron is made, at the bottom of which is placed a layer of plaster of Paris. On this is spread a mixture of one-half crushed glass and one-half stoneware, chinaware, bits of bricks or tiles, or other crushed refractory material, "massed glass," and this is covered by a thin layer of powdered glass. The mould is now introduced into the glass furnace, where the parts are welded into a compact body of complicated texture. The mould is then exposed for a very short time in a reverberatory furnace, where the flame imparts a brilliant polish to the glass surface or enamel. —V. C.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

Sheet Zinc, Application of, for Roofing and other Purposes. Seamon. Eng. and Mining J. **62**, [20], 461.
See under X., page 906.

PATENTS.

Kilns, Impts. in the Construction of, for Burning Limestone, Cement, and other Similar Materials. J. Foster, Carnlough, co. Antrim. Eng. Pat. 17,830, Aug. 12, 1896.

THE new kiln is provided with a superimposed arch, through which, by means of a shoot, the charging is effected. By this system of charging centrally from above, the upper chambers can be carried to any reasonable height, and an indefinitely large quantity of material may thus be subjected to the heat arising from the lower chamber. —V. C.

Artificial Stone, Impts. in the Production of. L. Preussner, Berlin. Eng. Pat. 8314, April 20, 1896.

THIS consists of a binding material and of filling masses. The latter may be sand, flint, barytes, and the like, or cellulose and the like, and (in the production of whetstones) emery may be added.

An analysis of the binding material yields the following percentage results:— $MgCl_2$, 31.72; $MgO + H_2O + CO_2$, 34.26; $Ca_3P_2O_8$, 8.37; $Mg_3P_2O_8$, 5.32; H_2O , 20.30. This is produced from strongly basic chloride of magnesium and soluble (acid) phosphate of lime or phosphoric acid. —V. C.

Building, Impts. in Plastic Substances [Antiseptic Plastic Substance] used for Building and Decorative Purposes. H. D. Lake, Middlesex. From M. Friedheim, Hamburg. Eng. Pat. 11,738, May 29, 1896.

THIS product may be shaped into bricks, gutters, bowls, &c. It contains an antiseptic chloride, such as "chloride of lime," which is said to constitute its value for sanitary building purposes. —V. C.

X.—METALLURGY.

Pyrometer for Blast-Furnace Tiewers. G. Braubach. Proc. Inst. Civil Eng. **126**, (iv.), 67. From Stahl und Eisen, 1896, 572.

WATER at constant pressure flows from a 70-gall. cistern placed just above the twyer-level, through an 8-mm. copper pipe placed across the goose-neck of the twyer. The temperature of the water before and after flowing through this pipe is measured by sensitive thermometers. The apparatus is standardised daily by means of a water pyrometer, and the flow of water through the copper tube is so regulated that a difference of 1° between the thermometers corresponds to 100° in the blast. This instrument has been in constant use at the works at Bendorf since March 1895, and is accurate to within ± 5 . —W. G. M.

Certain Metals and Alloys, Solution and Diffusion of, in Mercury. Part II. W. J. Humphreys. Proc. Chem. Soc. 1896, [170], 220.

THE author has extended this investigation (this Journal, 1896, 199) to aluminium, antimony, cadmium, magnesium, thallium, and a few alloys. Aluminium and antimony diffuse in mere traces. The cadmium amalgam heavier than mercury was not formed. The author considers that solution and diffusion in mercury may serve to distinguish between mixtures and compounds in the case of alloys. Metals that belong to the same group in Mendeléef's table increase in their power of solution and diffusion with their atomic weight.

Silver Amalgam, Ag_2Hg_8 ; Note on the Heat of Formation of the. F. T. Littleton. Proc. Chem. Soc. 1896, [170], 220.

IN a previous communication (Trans. 1895, **67**, 239) an account was given of a silver amalgam exhibiting remarkable behaviour on being moderately heated, swelling up as

if from the evolution of gas, and becoming hard, brittle, and crystalline in structure. It was noted that this behaviour was most marked when the silver and mercury were present in the ratio of 1 atom of the former to 4 of the latter, and that, when these metals were brought together, the silver, in the state of a fine crystalline powder (as reduced from the pulverulent chloride by zinc and a little hydrochloric acid), and the mercury simply poured over it, there was very considerable rise of temperature, amounting to 38° or 40°; so that the amalgam could not be borne on the palm of the hand without pain.

If the formula assumed for the amalgam be Ag_2Hg_3 , and the molecular weight be taken as 1,813.8 ($H = 1$), the heat evolved in the formation of one molecule is equal to about 3,432 units, the molecular weight being counted in grams, and the unit of heat as the heat required to raise the temperature of 1 gm. of water (at about 22°) by 1°. These determinations gave the values 3,395, 3,418, and 3,484. It is to be observed that the amalgam, just after its production, is a soft, pasty, semi-fluid mass. Calculating from Person's figures, for the latent heat of fluidity of the metals concerned, 1,813.8 grms. of the amalgam consist of 215.4 grms. of silver, the fusion of which would absorb 4,537 heat units and 1,598.4 grms. of mercury, the solidification of which would evolve 4,507 heat units.

Nickel and Nickel Steel. H. Wedding and Rudeloff. Verhändl. des Vereins zur Beförderung des Gewerbefleißes, Berlin, 1894—1896; Monit. Scient. 10, October 1896, 742—760.

A PRELIMINARY statement of the Committee appointed to inquire into the alloys of nickel was issued in 1894 (see this Journal, 1894, 13, 955). The present is an elaborate report with many tables of analyses and tests, and is divided into two parts, one relating to pure nickel and the other to nickel steel. Ordinary commercial nickel was operated upon, and after fusion, with the addition of a little magnesium prior to casting to remove oxygen, was cast into bars which contained per cent.:—Ni, 97—98; Co, 1—1.3; Fe, 0.3—0.6; Cu, 0.1; Mg, 0.1; Si, 0.06—0.1; and a trace of sulphur. The coefficient of linear expansion expressed in thousandths of a mm. per metre per 1° C. was found to agree well with the following formulæ—

$$\text{For cast bars (mean)} = 12.65 \pm 0.009 + (0.010 \pm 0.002) t,$$

$$\text{For forged bars (mean)} = 12.67 \pm 0.007 + (0.0085 \pm 0.0035) t,$$

where t is the temperature in Centigrade degrees. Hence the coefficient of dilatation is practically the same for cast and wrought nickel. The same remark may be made as to the electrical resistance of the two classes of material, the specific resistance (in microhms-centimetre), averaging 9, excluding two cases in which 1.2 per cent. of manganese was present and the resistance was 11.5. Tensile tests gave results that were somewhat variable among themselves, but showed a marked difference between the merely fused and the worked samples. Thus, in cast metal the elastic limit, breaking load, and extension, averaged respectively 3.5 and 9.2 tons per square inch and 4.7 per cent.; whilst in the wrought nickel the corresponding numbers were 18.35 and 29.5 tons per square inch and 17.9 per cent. The bars in which 1 per cent. of nickel was replaced by 1.2 per cent. of manganese gave the following noteworthy results:—For cast bars, 4.4 and 18.2 tons and 14.4 per cent.; and for wrought metal, 21.9 and 30.8 tons per square inch and 15.5 per cent. extension respectively.

Alloys of Nickel and Iron.—A series of test-pieces, free from carbon, was made, containing varying proportions of nickel from 0 to 100 per cent.; the principal impurity was cobalt, which increased in quantity with the percentage of nickel, but never exceeded 1 per cent. Of the other elements, the maximum percentages present were as follows: Cu = 0.1, Mn = 0.06, Mg = 0.09, Al = 0.07, Si = 0.1, and S = 0.02. The mean results of tensile tests are given in the following table.

TENSILE TESTS OF CAST FERRO-NICKEL BARS.

Nickel.	Load in Tons, per Sq. in. at		Modulus of Elasticity in Kilos. per Sq. Mm.	Elongations	
	Limit of Proportionality.	Rupture.		On 1-in. Length.	On 2-in. Length.
Per Cent.				Per Cent.	Per Cent.
0.05	3.8	29.6	32,525	36.8	29.7
0.76	3.9	29.4	29,706	25.1	20.6
1.01	4.5	21.4	21,050	31.8	25.4
2.05	6.5	23.5	20,710	26.1	22.7
3.01	10.2	25.8	20,070	23.4	20.0
3.98	10.5	25.8	20,178	29.1	17.6
4.92	12.4	28.3	19,930	12.9	10.8
7.84	14.5	33.7	19,280	11.1	9.6
15.60	10.2	26.0	16,200	0.9	0.6
29.71	4.0	6.3	12,300	2.8	2.2
50.60	3.8	24.0	14,400	37.9	36.1
93.52	2.6	21.1	17,400	20.1	19.0
98.56	2.3	19.4	16,870	18.2	17.1

From this table it is seen that the limit of proportionality increases with the percentage of nickel, until the latter attains to 10 per cent.; it then falls abruptly to 30 per cent. of Ni, and then more gradually. The tensile strength, however, reaches a second maximum at 60 per cent. of Ni, which is also the point of maximum elongation. The extension of the 15 per cent. alloy is practically *nil*. The fractures of the alloys containing 1—3 per cent. of Ni were granular; with an increasing percentage of nickel they were more and more crystalline, excepting the 60 per cent. alloy, in which the granular structure reappeared, and the 30 per cent. metal, in which the needle-like crystals showed traces of oxidation that would account for the inferior tenacity of the bar. The structure, however, may be either granular-crystalline or acicular; the former is best seen in the 16 per cent. alloy, and appears to be characteristic of the metals having the highest tenacity. A second series of tests (quoted in full) shows that the limit of proportionality was in all cases considerably raised by applying the load very gradually, and allowing the bar to remain under tension for two minutes before applying the next increment, which was, in every case, 0.6 ton per sq. in. Compression tests showed similar indications to those obtained by tension, excepting that the alloy which gave the highest result contained 16 per cent. instead of 8 per cent. of nickel. Test-pieces 15 mm. high and of the same diameter were submitted to the action of a falling weight, and the percentage reduction in length was measured after each blow. Twenty blows were delivered to each piece, three series of tests being made, in which the blows corresponded respectively to 5, 10, and 20 kilogrammetres per sq. cm. It was thus found that the resistance to shock varies in direct proportion to the percentage of nickel up to the 16 per cent. alloy; in the 30 per cent. metal it is equal to that of pure iron, and then increases slightly up to the 60 per cent. mixture, and finally falls again to the 30 per cent. level for pure nickel. In each individual test the effects of successive blows were less and less marked, especially as the proportion of nickel was increased; but this would be expected, as the method of testing was merely one of applying cold-work to the bars. Shearing tests showed variations which agreed with those observed in the compression-bars, only that the influence of nickel was less marked in the former case. Finally, the coefficients of dilatation were found to be about 11.56, 10.9, 10.3, and 12.61 for the materials containing 0, 4, 16, and 100 per cent. of nickel respectively, the full formula for the 16 per cent. alloy being—

$$10.30 \pm 0.05 + (0.0056 \pm 0.0015) t.$$

—W. G. M.

Steels, The Influence of Heat Treatment and Carbon upon the Solubility of Phosphorus in. E. D. Campbell and S. C. Babcock. Amer. Chem. J. 1896, 18, 719—723.

Owing to the brittleness of steel, due to phosphorus, being more marked when the carbon is high than when low, and in the same steel when it is hardened than when it is in its

annealed or normal state, experiments were made to ascertain if there was any relationship between the carbon and phosphorus compounds in the metal, and if the chemical condition of the phosphorus is changed by varying the heat treatment. Three samples of steel were used, containing 0.1, 0.37, and 0.73 per cent. of carbon, and 0.119, 0.160, and 0.114 per cent. of phosphorus respectively. The quantity of phosphorus in each of these metals in their annealed, normal, and hardened conditions was determined distinctively in respect (1) To the amount dissolved by neutral mercuric chloride, (2) To that insoluble in mercuric chloride but soluble in 4 per cent. hydrochloric acid, and (3) To that insoluble in both mercuric chloride and hydrochloric acid. From the results, the following facts are derived:—(1) With very low percentage of carbon, the effect of heat treatment upon the solubility of phosphorus is slight—probably if carbon were entirely absent there would be no effect; (2) with increase of carbon the effect of hardening is to diminish the solubility of the phosphorus; and (3) with high percentage of carbon the solubility is increased by slow cooling.

These three facts point to the probable formation, at a high temperature, of a compound of iron with carbon and phosphorus, soluble with difficulty, which is transformed on slow cooling into an easily soluble one. Since the difference in the chemical behaviour of phosphorus in hardened and annealed steels is as marked as that of carbon under similar conditions, it is not improbable that the heat absorbed or evolved in the transformation of one form into another, might account for one of the retardation points of Osmond in the same way that the transformation of carbon into cement carbon accounts for one of those points of recalcrescence.—A. W.

Steel, The Diffusion of Sulphides through. E. D. Campbell. Amer. Chem. J. 1896, 18, 707—719.

To ascertain the conditions best suited to the diffusion of iron sulphide through steel, experiments were conducted by melting differently prepared sulphides in open and closed cavities in bars of that metal. It was observed that the diffusion was dependent on the presence of an oxy-sulphide of iron, and to fully establish this the following experiments were performed:—

A pure normal sulphide of iron, free from oxide, was prepared by melting the ordinary sulphide in an atmosphere of sulphur for a lengthened period, and was heated for some time at a bright red heat in the cavities of the steel. The sulphide simply melted down, and showed no evidence of diffusion. A sub-sulphide was then prepared containing 5.84 per cent. of FeS and 92.41 per cent. of Fe₂S. This was also heated in the open and closed cavities, and the result showed that in the open hole it had sunk very slightly, whilst in the plugged hole there was no sign of diffusion. An oxy-sulphide of iron containing a ratio of FeS to FeO of 2.7 to 2, treated in a similar manner, disappeared rapidly, and the diffusion was complete in both cases in a very short time. Some of the same oxy-sulphide heated in a porcelain crucible placed near the bar of steel, showed no loss in weight, proving that volatilisation could not account for any loss of sulphide.

The sulphide diffused through the entire length of the bars, and not merely through the narrow sides between the cavities and the surface. This was proved by the blackening of asbestos plugs placed at the furthest end of the bar, due to the saturation with oxide of iron produced by the oxidation therein of the diffused sulphide. Experiments with sulphides of other metals showed that copper sulphide did not diffuse, and that a mixture of oxy-sulphide of iron and cuprous sulphide diffused almost completely. Both sulphides appeared to pass through the steel without decomposition. Nickel sulphide showed very little, if any, signs of diffusion.

The authors explain the above results by assuming that the extra mobility of the oxy-sulphide of iron enables it to travel through the pores of the heated metal. The rapidity of its absorption by the crucible in which it was made will support this view. The accumulation of the sulphide towards the lower part of the bar showed the influence of gravity, and also that the diffusion is a liquid and not a gaseous one.

The fact that cuprous sulphide would not diffuse except when mixed with oxy-sulphide of iron is also explained by the assumption that it is not sufficiently mobile when liquid to penetrate the fine pores of the steel, and increased mobility by the mixture enables it to do so.—A. W.

Sheet Zinc, Application of, for Roofing and other Purposes. Seamon. Eng. and Mining J. 62, [20], 461—462.

A TABLE is given of cost of roofing in Europe and America, based on current contract prices, and on the assumption that labour costs 50 per cent. more in America than in Europe. The cost per 100 sq. ft. varies, according to style of roofing and thickness of zinc, from 8.37 dols. to 12.20 dols. in Europe, and from 10.48 dols. to 15.61 dols. in America. A second table gives the comparative cost of laying and maintaining for 30 years, roofs of different materials, including interest on expenditure on original roof and on repairs; the figures are, in dols. per 100 sq. ft., zinc, 35.05; tinplate, 46.87; slate, 37.05; galvanised iron, 38.95; tiles, 39.75; lead, 58.80; copper, 84.00.

The coating formed on zinc by ordinary air containing carbonic acid is very tenacious and protective. Experiments showed that such coated zinc, exposed to the action of water containing 0.5 gm. of sulphurous or carbonic acid per litre, was dissolved at a rate which would require 300 years to completely dissolve a sheet of No. 13 zinc.

The amounts of carbon and of sulphur usually found in commercial zinc are without influence on its suitability for roofing. Iron above 0.13 per cent. makes the zinc too brittle to be properly rolled and bent. Lead up to 1 per cent. is beneficial, but above 1½ per cent. will not dissolve, and the excess collects and forms weak spots. Arsenic, antimony, cadmium, tin, and copper practically never occur in quantities sufficient to be injurious. The following table gives the impurities of a European zinc largely used for roofing, followed by those of nine samples of zinc from Missouri ores:—

Lead	0.708	0.6331	0.6295	0.6725	0.4105

Among other uses of zinc mentioned, are those for ornamental castings (statuettes, &c.) and metallic monuments—so-called "white bronze"—which are cast from spelter, and roughened on the surface by the sand blast.—J. T. D.

Alloys, Fusibility of Metallic. H. Gautier. Bull. Soc. d'Encouragement, Oct. 1896, 1233—1318.

THE author has examined a large number of alloys, and has arrived at the following conclusions:—

Alloys in no respect resemble glasses, as has sometimes been stated. They are crystalline substances formed either by the juxtaposition of the crystals of the constituent metals, as in the case of the alloys:—Tin-zinc, tin-bismuth, tin-lead, lead-antimony, cadmium-zinc, zinc-aluminium, and antimony-silver; or by the juxtaposition of the crystals of one of the metals with a definite compound, as in alloys of:—Tin-copper, antimony-copper, aluminium-copper, lead-copper, bismuth-copper, tin-aluminium, tin-nickel, copper-nickel, zinc-antimony, aluminium-silver, and antimony-aluminium.

Other much more complex alloys may form isomorphous mixtures, either because the metals themselves are really

isomorphous—bismuth-antimony, silver-gold,—or because they form isomorphous combinations with one of the metals; this appears to be the case with the alloys:—Zinc-copper, zinc-silver, tin-silver, cadmium-silver, and tin-antimony.

The fusing point of an alloy is nearly always lower than that of the least fusible of its constituents; the only exceptions to this rule are certain alloys of gold with aluminium, and the greater number of those of antimony with aluminium.

The solidification of an alloy of given composition always begins at the same temperature. Except in the case of isomorphous mixtures, either pure metal or a definite compound separates out on solidification. This deposit causes a variation in the composition of the still liquid portion to take place, and the solidification can only continue if the temperature is still further lowered, and so on; hence the temperature does not remain constant during the whole process of solidification. Again, if the density of the substance which separates out is notably different from that of the remaining liquid, it collects either at the top or bottom of the crucible, and, after cooling, forms an ingot, the composition of which varies from top to bottom, *i.e.*, from a metal or definite compound to an alloy of minimum fusing point. This is the well-known phenomenon of "liquation."

Solidification takes place at constant temperatures either when the composition of the alloy corresponds to a definite compound (in this case the separation of the solid does not modify the composition of the remaining liquid), or when the composition corresponds to an angular point on the fusibility curve, *i.e.*, to a eutectic alloy (in this case the metals which separate out correspond to the two branches of the curve which cut at the point, and the composition of the liquid bath still remains constant).

Isomorphous mixtures sometimes solidify at constant temperature, and sometimes at a gradually decreasing temperature.

Eutectic and isomorphous alloys do not exhibit a crystalline fracture, even after polishing and treatment with an appropriate etching reagent, as the crystals of these alloys are so extremely fine that they give to the fracture a peculiar appearance resembling that of a vitreous mass.

—J. S.

PATENTS.

Metallic Alloy [Copper, Nickel, Zinc, and Antimony]. A New or Improved. W. Woolf, London, and J. Andrews, Birmingham. Eng. Pat. 22,137, Nov. 20, 1895.

An alloy of copper, "mixed nickel" (a copper-nickel alloy), spelter, regulus of antimony, and "copper flux," produced by melting together the copper and mixed nickel, and adding the other ingredients under a flux. The mixed nickel consists of 1 part of B.S. copper and 1 part of pure nickel; the "copper flux" is formed of 1 part of common salt, $\frac{1}{2}$ part of borax, and $1\frac{1}{2}$ parts of "sal-enixon."

—J. T. D.

Gold, An Improved Process of Extracting, from Refractory Auriferous Ores. [Alloying with Lead.] H. S. Maxim, London. Eng. Pat. 22,812, Nov. 28, 1895.

ORES containing a high percentage of gold, but containing substances which prevent the ordinary processes from being applicable, are treated by a process resembling amalgamation, with lead at a high temperature, in a rotatory apparatus containing a number of iron balls, which assist in the subdivision and thorough mixture of the pulverised ore and melted lead, whilst an atmosphere of hydrogen or other reducing gas prevents oxidation. The reducing atmosphere, the ponding or mixing operation, and the form of apparatus described and figured in the patent, are all subjects of claim.—J. T. D.

Sodium or Potassium, Impts. in or connected with the Manufacture of. [Crucible of Nickel or Cobalt.] J. A. Kendall, Surrey. Eng. Pat. 23,045, Dec. 2, 1895.

CARBON and a carbamate or hydrate of the alkali metal to be obtained, are submitted to a high temperature in a vessel

of nickel or cobalt, and surrounded or mainly surrounded by another vessel or jacket, so as to enclose a space into which hydrogen or a similar gas is passed.—A. S.

Sulphide Ores containing Zinc and other Metals, An Improved Process for Treating [for Zinc and Silver]. T. Parker, Wolverhampton, and J. Pullman, London. Eng. Pat. 23,543, Dec. 9, 1895.

THE pulverised ores are treated with strong hydrochloric acid at a temperature of 90° C., the clear solution made and maintained neutral by zinc carbonate, lead chloride deposited from the cooled solution and treated for lead, and the zinc extracted by electrolysis. The treatment with zinc carbonate (or with a little cold bleach liquor) frees the solution from any iron it may contain. The residue from the process, after further lixiviation with hydrochloric acid, is treated with sodium hyposulphite or strong brine to recover silver.—J. T. D.

Copper, Impts. in the Method and Means for obtaining, from Copper Ores. C. A. Burghardt, Manchester, and G. Rigg, Eccles. Eng. Pat. 9388, May 4, 1896.

THE ore, well roasted and crushed, is treated with strong solution of ammonium carbonate in which has been dissolved zinc oxide to the amount of 4,000 or 5,000 grains of zinc per gallon, loss of ammonia being prevented by a layer of petroleum. The copper is recovered from the settled solution by zinc or zinc and tin plates, and the zinc from time to time removed by electrolysis from the liquor, which is used over and over again.—J. T. D.

Amalgamating Apparatus for Extracting Gold and Silver from their Ores, Impts. in and connected with. J. W. Clarke, London. Eng. Pat. 22,715, Oct. 13, 1896.

A DISHED bed-plate containing the requisite mercury, in which work two or more fluted rollers partially immersed in the mercury, and all rotating at slightly different rates. Thus the ore is carried under the mercury, to the rear, and to a rake, which works transversely, and on which a number of jets of water play, to separate the tailings from any mercury which they may carry with them. Between the rollers and the rake is a vertical splash-guard to catch mercury thrown off by the last roller. An electric current passes continually through the mercury, to lessen the loss by "flouring" or "sickening."—J. T. D.

Engraved Copper Plates, An Improved Process for the Protection of, by the Use of Nickel. K. P. Beck and W. Moss, Hanley, and A. Hioros, Handsworth. Eng. Pat. 20,545, Oct. 31, 1896.

XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

(A.)—ELECTRO-CHEMISTRY.

Porous Carbon Cylinders for Electrolytic Work. [Organic Electro-synthetic Work, &c.] W. Löb. Zeits. f. Elektrochem. 1896, 3, 185—187.

IN the form in which Bunsen first introduced the cell which bears his name, it contained no porous cylinder. The carbon was in the form of a hollow cylinder containing the oxidising liquid, and this dipped directly into the dilute acid containing the zinc. The carbon rod and porous cylinder were only introduced later.

For the purpose of performing organic electro-syntheses without a primary battery (the organic substance forming part of the cell itself), the author has endeavoured to get rid of the usual porous cell, which offers considerable resistance. The most convenient way of doing this is to use moulded carbon cylinders as porous cells. In its conducting power carbon nearly approaches the metals, and when used in this way it acts as an intermediate conductor. Electrolysis takes place on both sides of the carbon cylinder; if the anode be immersed in the outer liquid, the outside of the cylinder plays the part of a cathode and the inside that of an anode. Its behaviour, then, is twofold. It behaves as a porous

diaphragm, through which ions pass freely. It also behaves as a solid conductor, of which the two surfaces act as anode and cathode respectively. For example:—An anode of platinum foil is immersed in a beaker containing dilute sulphuric acid; a hollow carbon cylinder containing copper sulphate is used as cathode. When the circuit is closed, oxygen is evolved at the anode. A few bubbles of hydrogen rise from the outside of the cylinder, but the amount is very small compared with the oxygen. After an hour, copper is found to be deposited on the inside of the cylinder, mainly on the part nearest to the anode. If we use as cathode a carbon rod dipping into the copper sulphate in the cylinder, copper is deposited on the cathode and also on the outside of the cylinder.

When a carbon cylinder is used directly as an electrode we might expect it to behave simply as a metallic electrode, the electrolytic action taking place only outside it, in the liquid which surrounds the cylinder and in which the second electrode is immersed. But experiments made by the author on this point indicate that the expectation is not realised. He concludes that when a carbon cylinder is used directly as a cathode (or anode), its whole surface—both inside and outside—behaves as a cathode (or anode). Lastly, he finds that when a cathode (or anode) is brought into metallic connection with a carbon cylinder, so that both are at the same potential, the whole system behaves as a cathode (or anode), the result being simply to increase the active surface.—D. E. J.

Electricity, Production of, by Chemical Means. E. Andreas. *Zeits. f. Elektrochem.* 1896, **3**, 188—189.

THE author has further investigated the behaviour of primary batteries, the action of which depends upon the continuous oxidation of hydrogen, carbon monoxide, &c. His results are mostly of a negative nature. He considers that the weak point in the batteries investigated by Borchers and himself is the use of electrodes which become dissolved as the battery acts, and that success can only be secured by the introduction of electrodes which do not go into solution during the oxidation of the gas used in the battery.

Electrical Primary Batteries, Impts. in or relating to. [Use of Treated Coal in Cell.] J. B. Whittemore, London. Eng. Pat. 18,549, Aug. 21, 1896.

A BLOCK of coal of about 5 lb. weight is taken, and on it is burned a small portion of sulphur, camphor, pitch, or analogous inflammable substance. The use is claimed, in the liquid of electrical primary battery cells, of pieces of the coal thus treated. Such cells are formed of an iron and carbon couple immersed in water, or if they are added to the nitric acid solution in a Bunsen cell, the zinc may be replaced by iron. An electromotive force of 1 volt is claimed for this cell. The specially "treated coal," it is said, when added in small quantity to the acid solution of an ordinary battery cell, increases the quantity and strength of the current therefrom to such an extent that iron can be used in place of zinc as the positive element in the cell.

Electrolytic Decomposition of Liquids, Impts. in or connected with Apparatus for. [Mercury Cathodes.] G. Bell and G. W. Bell, Liverpool. Eng. Pat. 20,542, Oct. 31, 1895.

THIS apparatus consists of three parts. The lower one, being the anode chamber, in which the brine or other liquid is decomposed, is separated by a porous partition, on which a layer of mercury rests, from the cathode chamber, in which caustic soda is produced. Above the chamber, and separated from it by a suitable diaphragm, is a gas chamber, in which the chlorine evolved in the anode compartment is collected. This chamber is separated from the anode compartment of the next series of cells above it by a metallic insulated diaphragm, and groups of these cells are thus arranged above each other. The cathode chambers are connected so that the caustic soda formed in the uppermost compartment becomes concentrated as it

flows down through the apparatus. The strength of the brine is maintained by adding salt to a separate vessel through which the solution from the anode compartment is circulated by a pump, where it is freed from chlorine by means of waste heat. The chambers described are preferably metallic, and lined with a protective coating of rubber or the like, and the tubes which carry off the chlorine serve also as supports to the porous diaphragms.

Storage Batteries, Impts. in. [Thin Negatives.] A. Preiss, Norwood, South Australia. Eng. Pat. 19,301, Sept. 1, 1896.

THE positives are of lead, and of the normal construction, but the negatives, which simply serve as conductors, are merely thin sheets of zinc, or aluminium, or any other suitable metal having the same superficial area as the positives. The electrolyte preferred is a dilute solution of sulphuric acid and sulphate of ammonia, having a density of 1.2. The cell is preferably formed of papier maché, and, by the improved construction, it is claimed that a reduction in weight of two-thirds can be effected.—G. H. R.

Electrolysis, A Process and Apparatus for Effecting. [Liquid Electrodes.] F. W. Golby, London. From O. Arlt, Goerlitz, Germany. Eng. Pat. 15,129, July 8, 1896.

THE apparatus consists of a tightly closed vessel with a bottom sloping to an outlet. The electrodes are introduced through perforations in the cover, and are packed to prevent the escape of gas, which is led off through a stand-pipe. The positive electrode consists generally of carbon, and the negative electrode of a jet or spray of mercury in the case of the electrolysis of brine or any other liquid metal or mixture of one or more liquid metals. The mercury which cannot flow off quickly enough is protected from the action of the brine by a layer of fluid, such as chloroform or bisulphide of carbon, which is heavier than the electrolyte, and is not acted on by the products of electrolysis; and the sodium amalgam formed is withdrawn from the vessel and treated with steam or water, with the formation of caustic soda and the regeneration of the mercury. Both electrodes may be fluid, and they are introduced into the electrolyte in jets and sprays of any convenient form, their introduction and withdrawal being so regulated that the electrical circuit is never broken.

—G. H. R.

Secondary Galvanic Batteries, Improved Plates for, and a Method of Producing the Same. [Block Plates.] C. Marschner, Berlin, Germany. Eng. Pat. 12,250, June 4, 1896.

THE binding agent consists of a solution of amber or other similar fossil resin, dissolved in alcohol or oil of turpentine and alcohol, and is added to the lead oxide so as to form a plastic mass, which is then spread out in a suitable frame of hard lead. The plates are dried at a moderate temperature, acidulated for a few days in a bath of dilute sulphuric acid, and finally shaped and arranged. The plates require no trellis support, and are very solid and elastic.—G. H. R.

Metals, Electric Furnaces for the Reduction and Refining of. W. Borchers. *Zeits. f. Elektrochem.* 1896, **3**, 189—192.

THE first of a series of papers on the development and construction of electric furnaces for metallurgical purposes. They may be divided into two great classes:—I. Furnaces of the first class depend upon what the author calls "resistance-heating." The principle here employed may be applied in two ways:—(1) The substance to be heated is itself introduced as a resistance into the circuit; (2) it is placed in contact with another substance, which is electrically heated. II. Furnaces of the second class depend upon what the author calls "arc-light heating." As a resistance has also to be overcome in the electric arc, the classification

is not free from objection, but for practical purposes it is intelligible and useful. Here again the principle may be applied in two ways:—(1) The substance to be heated forms one or both poles of an arc light; (2) it is placed in a space heated by the arc. For a given distance between the poles, a furnace of Class I. requires a large current, but only a low E.M.F., whereas a furnace of Class II. requires a high E.M.F., but only a small current. The present paper deals with furnaces of the kind I (1), in which the substance to be heated is introduced directly as a resistance into the circuit. We find an illustration of this principle as far back as 1815, in the Phil. Trans., where Pepys describes a sort of "electric cementation" experiment in which iron wire, in contact with diamond powder, is converted into steel. But the first practical application of the principle to the reduction of metals was made by the brothers Cowles in 1884. They intended it to be used for zinc as well as aluminium, but for the former purpose it has not been a success. Fig. 1 is a diagrammatic representation of a furnace intended for the reduction of aluminium, and Fig. 2 shows the form into which this furnace has now developed. The electrodes consist of carbon rods fixed in iron or copper holders, which are introduced into the furnace through cast-iron tubes. They are adjusted by screws and hand-wheels. In the position shown in the figure, two of the carbons project far enough to touch. The heating effect of the current here is very intense, and these two rods soon waste away. Meanwhile, the part of the mixture surrounding them has become heated, and by gradually withdrawing the electrodes, the whole of it can be submitted to the action of the current. The distance of the electrodes is regulated in accordance with the indications of the measuring instruments. When

Fig. 1.

Fig. 2.

the whole of the mixture is fused, the current is stopped and the next furnace is thrown into action. Not only the continuous current, but also the alternating current, can be used in this furnace; in fact, the latter gives a more uniform heating effect. This shows that the Cowles process is purely one of reduction, and that electrolysis plays no part in it.—D. E. J.

Metallic Zinc from Ores of Zinc, and Metallic Zinc and Metallic Copper from Zinc Ores containing Copper, and the Production of Oxygen Gas in the Cases specified; Impts. in a Process and Apparatus for the Electrolytic Production of. [Ammoniacal Bath.] C. A. Burghardt, Manchester, and G. Rigg, Eccles. Eng. Pat. 22,732, Nov. 28, 1895.

THE ores, which have been thoroughly oxidised by roasting, are ground and treated with a concentrated solution of either the normal carbonate, the sesquicarbonate, or the bicarbonate of ammonium, or a mixture of these; or a solution of ammonia gas in water may be employed, but in the latter case no oxygen is evolved in the later stages of

the process. The bath is covered with a layer of paraffin or other mineral oil of high flashing point and low viscosity, to prevent loss of ammonia, and a mechanical stirrer is set in motion. When all the oxides have been dissolved, the clear liquor is drawn off into another tank, and again covered with a layer of oil. The solution is freed from any iron it may contain by treatment, at about 40° C., with a certain proportion of hydrated oxide of tin, and the clear liquid is again drawn off into another tank. If copper be present, it is recovered by immersing in the bath plates of zinc, or, preferably, of zinc in contact with tin, and the copper deposited on the zinc strips easily, and is entirely free from oxides, owing to the layer of oil. The solution, freed from copper, is electrolysed in a bath covered with a layer of paraffin and provided with sheet zinc cathodes and tin or lead anodes. If a solution of the carbonates has been employed, the oxygen given off at the positive pole is collected and washed.—G. H. R.

Electrodes for Electrolytical Purposes, Impts. in. [Platinum Tubes.] W. Heraeus, Hanau-on-the-Main, Germany. Eng. Pat. 1144, Jan. 16, 1896.

THE electrodes are formed of thin tubes of platinum surrounding an accurately fitting core of copper or other good conductor. The tubes are connected together by conducting or non-conducting transverse top bars, and by a thin sheet of platinum in the intermediate spaces for the depth to which the tubes are immersed in the bath. The lower ends of the tubes are also closed with platinum. This composite electrode allows of the use of large currents with a small weight of platinum.—G. H. R.

White Lead, Impts. in the Manufacture of. A. B. Browne, Boston, U.S.A. Eng. Pat. 14,988, July 7, 1896.

A SOLUTION of a salt of an alkaline base, such as sodium nitrate, is electrolysed in a vessel divided by porous partitions into three compartments. The central chamber contains excess of the electrolyte, whilst one end chamber

contains a pig-lead anode, and the other a cathode, preferably of copper. The solution under electrolysis is decomposed; the nitric acid attacks the lead anode, forming nitrate of lead, whilst the caustic soda goes to the cathode. The two solutions are drawn off into tanks and then mixed, thus forming sodium nitrate (for use over again) and precipitating the lead as hydrate. The lead hydrate is filtered off and carbonated to form basic amorphous carbonate of lead.

Means are described for preventing the re-commingling of the acid and alkali in the electrolyser, and also for preventing the formation of objectionable sub-salts of lead. (See also this Journal, 1896, 207.)—A. S.

Enamel Paint and Combination of Materials for Composing same. [Shellac, Copaiba Balsam, Camphor, and Dextrin.] G. W. N. Hamilton, Albert Park, Victoria. Eng. Pat. 19,318, Sept. 1, 1896.

This is composed of 1 gall. of methylated spirit, 3 lb. of shellac, 1 lb. of white pine resin or copaiba, 4 oz. of camphor, 4 oz. of gum-arabic or dextrin, and a sufficiency of pigment, all mixed together and strained. The gum-arabic is dissolved separately in a little water. The material dries in about 10 minutes, giving a perfectly smooth surface, and is particularly suited for painting ships' bottoms, &c.—F. H. (B.)—RESINS, VARNISHES.

Resin, Mayr's Method of Tapping Trees for the Extraction of. Chem. Rev. Fett-u. Harz-Ind. 3, [19], 203—205.

To prevent the loss of volatile oil, estimated at 50 per cent., and minimise the drying up of the wood occasioned by the ordinary method of tapping resinous trees, it is proposed to proceed as follows:—A hole is first bored in an upward direction, about 12 ins. from the ground, through the bark and into the wood, on the S.E. side of the tree. Above this aperture a vertical axe cut, some 50 cm. long, is made in the bark, and, by means of a tool inserted through the cut, the bark is loosened from the wood on either side, so that a free space of oval form is left between them, any loose woody tissue being scraped out with the tool. This space is kept open by the insertion of folded strips of sheet metal forming small V-shaped troughs, arranged in diverging pairs thus Λ , to drain the exuding sap from the cleft, so that it runs down between the bark and the wood, and is conveyed by a pair of converging (V) troughs into an effluent placed in the hole at the lower extremity. The vessel to catch the droppings is covered by a funnel, and the whole arrangement keeps the resin clean and minimises evaporation. The bulging of the bark, caused by the underlying troughs, diverts the water flowing down the trunk away from the collecting vessel, the effect being increased by removing a few scales of bark on either side of the bulge.

The second year, the troughs are removed, and the same operation is repeated at a higher level, the bark over the abandoned surface being nailed down to heal; in the case of hard-barked resinous trees the outer scales of bark should be partly removed before tapping.—C. S.

New or Improved Chemical Substance, and the Application thereof to Industrial Purposes, such as Rubber, Gutta-Percha, or Celluloid Substitutes, Insulations of Electrical Conductors, Coverings for Ships' Bottoms, or Wall and Floor Coverings. P. C. D. Castle, Liverpool. Eng. Pat. 19,130, Oct. 11, 1895.

This consists "in the preparation and application of the gum produced from the kernels of the *cratonia siliqua* (locust tree) as a substitute, solvent, diluent, or joint ingredient of india-rubber, gutta-percha, or celluloid." The two substances may be mixed in any proportions, may be vulcanised or not, and the rubber itself may be replaced by oxidised linseed oil. For the walls or floors of rooms the

composition can either be used as a cement to hold the woodwork together, or the whole floor may be coated with it after the manner of asphalt. (See also this Journal, 1894, 410, and 1895, 632.)—F. H. L.

Nitro Compounds suitable for Moulding, and for Coatings. Varnishes, and the like; Impts. in. W. F. Read, Addlestone, Surrey, and E. J. V. Earle, London. Eng. Pat. 21,995, Nov. 19, 1895.

Ons mainly composed of linolen, such as linseed, poppy or nut oil, or those containing a large proportion of ricinolen, such as castor oil, are nitrated in the usual way. The nitro products obtained are semi-fluid. These are mixed with finely powdered carbonates of the alkalis or alkaline earths (e.g. chalk) in quantity a little more than sufficient to neutralise the free acids remaining in the nitro compounds. The excess of carbonates is removed by heating to 93° C. and allowing to settle. The substance thus prepared is mixed in varying quantities with compounds of nitro-cellulose (parkesine, xylonite, celluloid, &c.), the latter being thus rendered less hard and brittle. The mixing is carried out by malaxation at a temperature not exceeding 100° C. Should the compound be required as a varnish or in solution, the ingredients may be added direct to the solvent, as ordinary solvents of nitrocellulose are also solvents of nitrolinolein and nitroricinolein.—W. P. S.

XIV.—TANNING, LEATHER, GLUE, SIZE.

Fermentation Phenomena in Tan Liquors. F. Andreasch. (Imp. Research Laboratory, Vienna.) Der Gerber, 1895, 21, [504, 505, 506], 193—220.

TANNING belongs to those industries in which the decomposition of organic materials by micro-organisms plays an important rôle.

The object of the article is to give a more exact account of those decompositions which take place in the tan liquors during the tanning process, with formation of a series of organic acids in considerable quantities. These acids have considerable influence on the tanning process, and the matter is of importance to the practical man, as it is in his power to modify the changes going on in the liquors to his benefit. Some of these decompositions or fermentations, as we shall call them, are actually visible by the rapid formation of a pellicle on the surface of the liquor, or by evolution of gas, e.g., in myrabolans liquors, but, even when not visible, fermentations are almost always going on in the liquors.

In order to thoroughly investigate the matter it was a first condition to isolate the numerous micro-organisms occurring in tan liquors, to study their physiological action on the materials used in tanning, and to separate the important ones from those having no influence on the process.

The author gives an account of the methods he used in the research. For obtaining the pure cultures required, Hansen's method was used for the yeasts (*vide* Micro-organisms of Fermentation, A. Jørgensen, 1893, 28), Koch's gelatin plate method for the bacteria.

As nutrient media, the usual 10 per cent. peptone-gelatin was not as a rule so useful as beer-wort gelatin (10 per cent.); in special cases 3—4 per cent. of alcohol was added to this.

For Hansen's method, unhopped beer wort, lager beer, and tannin infusions were used as media.

Gelatin and agar naturally do not admit of the addition of any tannin, nor does the gelatinous silicic acid. Fortunately the tannin may be replaced in the solid media by carbohydrates, such as glucose and milk sugar; best of all is a strong infusion of a tanning material from which the tannin has been removed by filtration through lüde powder; the filtrate may be used alone for liquid cultures. Glycerin peptone agar, milk serum gelatin, and potatoes were also used as solid media.

As intermediate materials between the gelatin cultures and the tannin liquor to be investigated, milk and beer were used. Following the bacteriological examination of the

liquors, chemical analyses were made to ascertain the changes which had occurred.

The bacteria present in tan liquors may be divided into the following groups:—

- A. Putrefactive bacteria.
- B. Water and air bacteria.
- C. Strictly fermentive bacteria and yeasts.

A. *Putrefactive Bacteria*.—In this division are included most of the organisms existing on and introduced into the liquors with the hides. The author finds that these are chiefly of importance as furnishing nitrogen from the hide substance by peptonisation, which is then used up by the true ferments. Fermentation goes on much quicker in liquors containing skins than in those which do not contain them.

The following recognised putrefactive ferments have been met with in tan liquors:—*Bacillus fluorescens liquefaciens* (Flügge); *B. megatherium* (De Bary); *B. Subtilis* (Ehrenberg); *Potato bacillus*; *B. Mesentericus fuscus* (Flügge); *B. Mycoides* (Flügge); *B. Viscosus* (Frankland); *B. liquidus* (Frankland); *Gas-forming Bacillus* (Eisenberg); *White Bacillus* (Maschek); *Proteus Vulgaris*, *Proteus mirabilis* (Hauser); *Bacillus butyricus* (Hueppe); *White Streptococcus* (Maschek); *Worm-shaped Streptococcus* (Maschek); *Grey Coccus* (Maschek).

Besides these known species there are other yet undescribed but putrefactive organisms, most of which have a similar effect on the subsequent fermentation. They naturally occur most numerous in the weak liquor. As an example of the way certain bacteria get into a tannery, the following example is given:—The waste water of a large works discharged into the neighbouring river was found to contain large numbers of *Proteus Vulgaris* and *B. fluorescens liquefaciens*; the same bacteria were found not only in the water but in the limes and tan liquors of a tannery a mile down stream, drawing its water from the same river. Where the cold-sweat process of unhairing is used, a still larger number of putrefactive organisms are found in the liquors.

B.—*Water and air bacteria*, as a rule, are of small consequence to the tanner, though some grow well, even in the presence of 25–30 per cent. of tannin, and by using up the proteids and carbohydrates of the liquors, and thus overgrowing the true ferments, they exert an influence on the tanning process.

In 120 samples from different tanneries, the following organisms were found:—*Bacillus Aerogenes* (Miller); *Bacterium Zuroianum* (List); *Bacterium Luteum* (List); *Bacillus Ochraceus*; *Bacillus Flavocitraceus* (Adametz-Wickman); *Bacillus fluorescens putridus* (Flügge); *Red Bacillus* (Eisenberg); *White Bacillus* (Eisenberg); *Orange-red Water Bacillus* (Adametz-Wickman); *Citron-yellow Bacillus* (Maschek); *Gas-forming Bacillus III.*, from dung bates and bran drench. *B. prodigiosus*; *Red Coccus* (Maschek); *Schlämpe Micrococcus* (Bräutigam); *Micrococcus luteus* (Cohn); *Micrococcus flavus tardigradus* (Flügge); *Micrococcus Aurantiaceus* (Cohn); *Micrococcus fulvus* (Cohn); *M. Versicolor* (Flügge); *M. Candicans* (Flügge); *M. Fervidus* (Adametz-Wickman); *M. plumosus* (Bräutigam); *M. flavus liquefaciens* (Flügge); *M. flavus desidens* (Flügge); *Cream-coloured micrococcus* (List); *Diplococcus luteus* (Adametz). *Diplococcus liquefaciens flavus tardus*, *Pedococcus acidi lactici* (Lintner); *Pedococcus* (Beer sarcina) (Lintner); *Sarcina Aurantiacea* (Hansen); *Sarcina Lutea* (Hansen); *Chrenothrix Kühniana*.

Of these, *Pedococcus* and *Sarcina* produce small quantities of acids; the latter, with *M. flavus liquefaciens* and *Diplococcus luteus*, occur very frequently in tan liquors. *Chrenothrix Kühniana* is also found in fairly large numbers, but only when the liquors are prepared cold. *Bacillus III.* (*gas-forming*) occurs almost always in upper-leather tanneries, where the goods have been bated or bran-drenched; it is characterised by copious evolution of gas during its growth in all nutrient media examined. It was found that such organisms as *Bacillus prodigiosus* grew vigorously in canaigre, pine, and heolock liquors, owing to the presence of starch in quantities.

Of the moulds, those most frequently occurring are *Penicillium Glaucum*, which grows well on sour liquors. *Mucor Mucedo* grows on moist bark, and from thence the

spores get into the tannery, and *Oidium Lactis*, a frequent but not necessary adjunct to lactic acid fermentation. The moulds do not produce acids directly; they generally make their appearance after the liquors become sour, and produce small quantities of alcohol and CO₂. *Penicillium* also decomposes lactic acid. They act as carriers of the bacteria, which, adhering to the mould spores, are carried with them into the air and thence into other liquors.

Oakwood and quebracho extracts, which ferment with difficulty, owing to a lack of suitable nutrient material, are good growing ground for moulds. Their special function in the decomposition of tannins of a glucoside character will be described in a later research. It will be seen from the above-mentioned organisms that the souring of tan liquors is influenced by numerous factors, and is no regular fermentation such as alcoholic or acetic acid fermentation. A bacteriological examination of the liquors has shown a whole series of bacteria and fungi in the liquors, but chemical analysis shows the following to be the chief products:—Carbonic acid, ethyl alcohol, acetic acid, and lactic acid. Although all these are of equal theoretical importance, only the two latter need be considered, and the bacteriological research is much simplified by considering only those species which produce these two acids. Of the two, lactic swells the skins better than acetic acid.

The author has found no organism in tan liquors capable of fermenting glucoses direct to acetic acid. And he considers that the production of this acid in the liquors is the result of two distinct processes—(1) the formation of alcohol; (2) the oxidation of the alcohol to acetic acid; that lactic and acetic acids are the result of entirely different chemical processes and are produced by different organisms. The production of alcohol and acids will be considered under the third heading.—J. T. W.

Preparing Hides for Tanning, Impts. in Lyes or Liquors for. [Cultivation of Bacteria of Dog and Bird Dung.] C. D. Abel, London. From *The Chemisch-techn. und Hygien. Inst.* (Popp and Becker), Frankfurt a/Main, Germany. Eng. Pat. 21,720, Nov. 15, 1896.

The use of dog, pigeon, or poultry dung as a bate after liming, is apt to give irregular results, especially under unfavourable atmospheric conditions, and a staining of the hides may often take place. It is found that the action of these liquors is traceable to the influence of certain bacteria, which may be cultivated on gelatin plates or otherwise; usually there are also detrimental bacteria present, which are liable to propagate at a far greater rate than the others under certain conditions—a fact that accounts for the non-reliability of ordinary water. Three favourable bacteria are described, of which pure cultures may be prepared. In practice, the parings from the flesh side of the hides (ordinarily a waste product) are boiled with an equal weight of water for half an hour by means of injected steam in a covered vessel. Concentrated sodium carbonate solution is then added until the reaction is slightly alkaline, and the liquor is cooled down to 35° C., after which there is added the pure culture obtained by the gelatin plate process (with dilution), and by the further treatment corresponding to the peculiarities of the bacteria; the whole is then allowed to stand, and covered up from a period of from 12 hours to five days, according to season and temperature. The hides or skins are dipped for a short time in the concentrated decoction, or for a longer time in a diluted liquor, the time depending upon the state of development of the bacteria. The further treatment is the same as that when dung is used, except that the duration is shorter.

Instead of using a pure culture, a dog dung (preferably of the white kind; this being found most effective) may be used, and so treated that only the useful bacteria are allowed to propagate. In the presence of 0.5 per cent. of dilute sulphuric acid, the useful bacteria are the most enduring, the others being killed. With 0.5 per cent. of carbonate of soda the two kinds develop equally, and with 1 per cent.,

the useful bacteria sufficiently preponderate. For preservation, sterilised bran or flour is inoculated with definite quantities of the pure cultures, and the water is reduced by drying or pressure to about 10 or 12 per cent. Sterilised cakes containing a definite proportion of the bacteria may thus be prepared. Or, after the bacteria have been properly developed, they may be killed by heating the liquid; for if a sufficient proportion of their products has been produced, the liquor is found to be as effective as if it contained the living bacteria.—W. G. M.

Tanning of Skins, Improved Process for the [under Hydraulic Pressure]. R. W. James, London. From S. Alimonda, Spezia, Italy. Eng. Pat. 20,154, Sept. 11, 1896.

The skins are prepared in the usual way and placed in the ordinary tanning liquors contained in a brass vat, which is then firmly closed. The contents are subjected to hydraulic pressure, amounting to about five or six atmospheres. About once a day the tanning liquid is strengthened or partly renewed, until, after 15 to 20 days for calves' skins, or 50 to 60 days for cows' skins, the operation is complete.

PATENT.

Manure, Impls. in the Manufacture of. [Humus from Turf, &c.] N. F. B. de Merecy, La Faloise, France. Eng. Pat. 6405, March 23, 1896.

ARTIFICIAL humate of lime is made by working peat or turf into a pulp with a sufficient quantity of water, and mixing the resulting bath with the necessary proportion of slaked lime made up with water into milk of lime. A flaky precipitate is formed, which may be separated by the filter-press and air-dried. The filtrate should give no further precipitate with lime-water. The precipitated humus should be clear brown, and may be associated with superphosphate or any other manure before use.—W. G. M.

XVI.—SUGAR, STARCH, GUM, Etc.

Sugar Industry, Progress in, for the Second Quarter of 1896. Dingl. Polyt. J. 1896, 302, 64—70.

Loss in Dry Solids of Beet Pulp on Pressing and Drying.—Results of the loss in nutriment and in dry solids in beet pulp on pressing and drying vary within wide limits according to the varying conditions in each sugar works. During the campaigns 1892-93 to 1895-96 inclusive, Rydlowski (Die deutsche Zuckerind. 1896, 21, 934) has made analyses and calculated the loss for the sugar works at Wasserleben a. H. The drier, heated with brown coal, was a *Büttner-Meyer*, and gave dried pulp of 12 to 13 per cent. of moisture. For the whole period 3,010,430 centner of beets were worked, representing 197,133·87 centner of dry solids, while the dried pulp contained only 177,399·35 centner, being a loss of 0·65 per cent. on the beets, or of 10·01 per cent. on the dry substance. Of this, 0·16 per cent. on the beets, or 2·54 per cent. on the dry solids, was due to the drying process, the rest to pressing.

Preparing Molasses Pulp.—A communication by A. Stift (Oester.-ungar. Zeits. Zuckerind. Landw. 1896, 25, 224) gives the result of a practical test at the Aes sugar works of the process of L. Szyfer, patented under the name of J. Natanson, for preparing molasses pulp. Full-weight molasses at 70 R. (87·5 °C.) was passed for 3 hours through a battery of 10 vats containing the cold pulp, the water driven off being run to waste; but as it contained 31·5 per cent. of potash on the ash, it might, if concentrated, be used as manure. The molasses was drained off and the pulp dried in the centrifugal machine. Although in this instance the beet pulp had previously lain for five

days and had become sour the result was satisfactory, and it was still sound at the end of three months. Cattle ate it eagerly (5 kilos. each animal per day), no laxative action being observed.

Apparatus for Subjecting Atomised Fluids to the Action of Gases.—C. H. Knoop (Ger. Pat. 85,820, March 5, 1895). For carrying out the process described in Patent No. 80,392.

Saturation Vessel for Limed Sugar Juice.—C. H. Knoop (Ger. Pat. 86,815, March 3, 1895). The juice (in Ger. Pat. 80,392) is forced into a holder against conical bodies, from which it rebounds in a finely divided condition, while the current of carbonic acid, which has already acted on the collected juice, is led through cross plates, and rises in the holder. The object of the present invention is a form of vessel suitable for carrying out the process, and is characterised in that the current of carbonic acid rises from trumpet-shaped mouthpieces arranged immediately under the juice atomisers, so that the juice finds itself in a finely divided condition in a conical jet of carbonic acid. The action of the gas on the limed juice is consequently extremely intense.

Fills for Osmose Frames.—Th. Koydl (Ger. Pat. 85,887, Sept. 4, 1894). A novel fill for the frames of osmose apparatus is described, by which a fault hitherto unavoidable in osmosing is completely removed. This fault is met with when the molasses, even when previously proposed fills are employed, pours in thick layers through the apparatus and the expected duty is incompletely fulfilled, for the osmosis can only take place, as is well known, where the molasses is in contact with the paper. This diminished duty is still more influenced in the existing plant, working for the most part without fills, when, as frequently happens, adjacent papers come into contact. According to the invention, the fills consist of hollow or solid plates, provided with grooves or ridges, which are placed in the osmose frames so as to fill the central part and leave only a small space free; thus the molasses is forced to flow through the apparatus in thin layers, while, in addition, the contact of adjacent sheets is prevented.

Evaporating Apparatus.—Gebr. Forstreuter (Ger. Pat. 86,271, April 28, 1895). In previous constructions of vacuum pans, which allowed of a gradual increase of the heating surface, there is for each stage of the heating system a separate steam inlet and a separate steam and water outlet, with its attendant shut-off for each stage. Certainty in working is thereby greatly lessened, and mistakes are very possible on the part of the panman, who has to attend to two independent valves. To avoid uncertainty and hasten the evaporation of liquids to the crystallising point, a heating system is constructed in the vacuum apparatus, consisting of a number of pairs of tubes or coils one above the other, which start from and end either in the centre of the pan or outside, in cylinders in which pistons may be arranged so that, with the increase in the height of the liquid, extra heat with heating surface reaches the liquid.

Process for Preparing Crystals in Refineries.—Th. Drost (Suppl. to Ger. Pat. 58,070, Dec. 25, 1889. Ger. Pat. 86,255, Nov. 11, 1891, expires Dec. 24, 1904). The process is characterised, first, by the use of purified refinery syrup, which has been brought to the necessary concentration, a specific gravity of 1·325, either during the liquoring of the sugar to be washed in the centrifugal, or by adding massecuite or raw sugar; or, second, by the use of a cleare prepared by the addition of purified refinery liquor or water to reduce massecuite either crystallised already or near the point of crystallising.

Automatic Tube-Cleaner for Evaporating Apparatus and Boilers.—A. D. Lagrelle and C. H. Chantrelle (Aus. Pat. 16—847, Jan. 25, 1896). This arrangement consists essentially of a floating or non-floating body placed in the tubes of an evaporating apparatus, and which receives an up and down or swinging or rotatory motion from the boiling liquid itself, and by rubbing against the inner walls of these tubes prevents any deposit thereon.

Process for Preparing Refined Sugar in Bars from Raw.—L. Ste. Ele. Fontenilles and Desormeaux (Aus. Pat. 46—1057, Oct. 24, 1895). This process has some points in common with known processes, but differs essentially in others, and is characterised by the following claims:—

(a) Heating of the vessel in which the solution, purification, and concentration of the sugar takes place by a water-bath or other heating arrangement which does not produce a higher temperature than 100° C. in contact with the walls of the vessel; (b) the crystallisation of the massecuite takes place in vessels of convenient size, which rest on a perforated bottom; (c) the crystallised mass, when drained, is broken up for conversion into bars or lumps and (d) agitated in a closed vessel with water in case the addition of water is necessary, in consequence of slow draining, to give the mass the requisite consistence for pressing into bars or lumps.

Process for Purifying Molasses, Syrup, or other Sugar Solutions.—G. E. Cassel and D. Kempe (Aus. Pat. 46—1251, March 5, 1896). According to this process the constituents possessing an unpleasant smell and taste are to be removed from molasses, syrup, and other sugar solutions. The molasses has an alkali or calcium sulphite, containing excess of sulphurous acid, added to it, and is then warmed. The action of the sulphite is increased by heating to 100° C. or higher; in the latter case in a closed vessel under pressure. Concentration of the liquor is of no importance. The excess of sulphurous acid may be added any time before the treatment, and, after this is over, any excess of lime remaining may be removed by carbonic acid.

The Use of Soda in the Manufacture of Cane Sugar.—(From the report by Dr. W. Krüger, Die deutsche Zuckerind. 1896, 21, 933.) There have been various attempts made to remove the disadvantages, caused by the salts of organic acids in the juice, attending the use of lime (incrustations in the evaporating apparatus, bad boiling, the large quantity of molasses), chiefly depending on preparations of phosphoric acid, but also by means of soda. According to Winter, it is advisable to limit as far as possible the formation of lime salts in the Indian cane-sugar works during defecation. In the defecation in general practice the action of the chalk is to throw down the precipitable substances of the cane-juice and to neutralise the organic acids. Winter now recommends defecation with lime and neutralisation with soda-lye. The advantages of this procedure are, it is said: slight incrustation, quicker evaporation in the triple effect, higher yields in first product, sharp, hard, and dry grain; in the syrups, better grain, and for the most part a higher yield.

Separation of Cane-Juice under Pressure.—Pohlmann (Centralblatt Zuckerind. d. Welt, 1896, 4, 659) gives an account of the saturation under pressure as carried out at Eva Mill, Hawaii. The limed juice is exposed to a temperature of about 122° C. at a pressure of two atmospheres, before passing to the settling tanks. In this way more lime is used than by open settling pans, and on the surface of the juice in the settling tanks a scum collects which must be removed. The principal part of the impurities quickly falls to the bottom. This is so abundant as often to require 2 sq. ft. of surface in the filter-press for a ton of canes. The dry cake is about 1 per cent. on the weight of cane. The superheated juice shows an increase in quotient of 3½ to 4, with a purity of cane-juice of 86. The most noteworthy property of the superheated juice is its freedom from "gum," in consequence of which it evaporates quickly and boils easily. The centrifugal syrup, with an average purity of 72, was not sticky, and could be boiled to grain in the vacuum pan, spinning well, and giving a sugar of 92 polarisation. In the previous year the syrup spun off could not be boiled to grain. The success of the process is further shown in the fact that this year the cane gave a higher yield by mulling than in the previous year on the same quality with diffusion, in spite of the higher extraction of the latter method.—L. J. de W.

Dextrose from Different Sources, The Identity of; with Special Reference to the Cupric Oxide Reducing Power. C. O'Sullivan and A. L. Stern. Proc. Chem. Soc. 1896, [170], 218.

DEXTROSE was prepared from sugar (cane and beet), starch, and lactose, and the optical activity, the cupric oxide reducing power, and the specific gravity of the aqueous solutions of each specimen determined. These factors were found to be the same for each of the different specimens of

dextrose, and consequently from this evidence it is concluded that the dextroses from various sources are identical.

The figures obtained for the cupric oxide reducing power are practically the same as Allihn's, which are in common use in Germany, although the former were obtained by proceeding according to the directions previously given by O'Sullivan, which, however, do not differ materially from Allihn's. A modified form of filtering tube is described, which was found to possess several advantages.

Starch, Yield from Potatoes, 1896 Crop. Zeits. f. Spiritusind. 19, [18], 385.

THE percentage of starch yielded by the potatoes of the 1896 crop (Germany) is reported to be unusually low, averaging about 12 per cent., as compared with 14 per cent. for 1894-95, even the small potatoes thrown out from the cooking grades showing the remarkably low average of 12 to 15 per cent.

It is considered important, both for the producer and starch-maker, that the prices should be fixed per unit of starch, since this would enable the latter to estimate the probable yield of starch products obtainable, and to pay for the raw material accordingly.—C. S.

XVII.—BREWING, WINES, SPIRITS, Etc.

Brandy, Composition of. Lussan. Monit. Scient. 1896, 10, 785—788.

THE following are the analyses of five new brandies (1895), the so-called impurities being expressed in milligrams per 100 c.c. of absolute alcohol. The sum of these impurities is called the "coefficient of impurities," and should always be over 340:—

	1.	2.	3.	4.	5.
Alcohol per cent.	67.7	64.8	66.1	67.0	70.2
<i>Impurities in mgrms. per 100 c.c. of Absolute Alcohol.</i>					
Acid (as acetic)	50.6	32.5	29.4	25.0	30.7
Aldehyde (as acetic)	5.9	7.4	15.9	14.0	46.1
Furfural	1.3	1.1	0.9	3.8	3.0
Ethers	158.3	131.8	98.4	77.4	287.7
Higher alcohols	151.9	167.7	267.4	222.0	159.0
Coefficient of impurity	367.0	349.5	412.0	342.2	526.5

The impurities may be divided into two groups: (1) oxidation products, acid and aldehyde; and (2) the ethers and the higher alcohols; and as the former group increases with the age of the brandy, its determination is of importance for the valuation of brandies. The percentage of acid and aldehyde in the above analyses, calculated on 100 parts of total impurities varies between 10.9 and 15.4, the mean being 12.9. This number is called the "coefficient of oxidation." The analyses of four brandies of the year 1893 show coefficients of impurities varying between 359.5 and 521.4 and coefficients of oxidation varying between 18.1 and 25.0.

The following are analyses of some older brandies:—

	1878.	1875.	1860.	1845.	1810.
Alcohol, per cent.	61.8	61.4	47.5	49.1	52.0
<i>Impurities expressed as above.</i>					
Acid.....	105.9	114.0	202.1	146.7	127.0
Aldehyde.....	26.0	28.9	48.1	31.4	44.0
Furfural.....	1.3	1.0	1.3	0.7	1.1
Ethers.....	127.0	144.0	133.3	125.5	132.0
Higher alcohols.....	194.6	173.6	345.4	203.5	175.1
Coefficient of impurity	154.8	161.8	730.1	507.8	479.2
Coefficient of oxidation	28.0	30.0	34.2	35.0	36.0

It will be seen from the above that although the numbers representing the ethers and higher alcohols vary considerably in different samples, and not in proportion to the age, the coefficient of oxidation gradually increases with the age of the sample, so that the latter may be at least approximately determined from this number. Thus, new brandies have a coefficient of oxidation of about 11—15, this number increasing fairly rapidly during the first years, but not exceeding 36 in a brandy 50 years old. Brandies to which alcohol has been added, and those obtained by the distillation of alcohol with grape husks, give very different results on analysis. The simple addition of alcohol will evidently reduce the coefficient of impurities. In other cases the coefficient of oxidation will be raised. The following are analyses of "doctored" brandies, of which D was obtained by distillation of alcohol with grape husks:—

	A.	B.	C.	D.
Alcohol, per cent.	47.5	48.0	35.3	50.3
<i>Impurities expressed as above.</i>				
Acid.....	50.5	80.0	20.4	160.8
Aldehyde.....	0.4	9.8	2.8	35.8
Furfural.....	0.1	0.2	0.1	1.2
Ethers.....	25.8	25.6	13.4	153.0
Higher alcohols.....	10.5	11.3	Traces	57.3
Coefficient of impurities	87.3	126.9	36.7	408.1
Coefficient of oxidation	58.3	70.7	63.0	18.0

—A. K. M.

Sherry Wine. E. W. Lucas. Pharm. J. 1896, 57, 397.

The British Pharmacopœia directs that sherry wine used in the preparation of the official wines should contain about 17 per cent. of absolute alcohol, but the author, on examination of some samples, found that the quantity present was generally only 13 to 14 per cent. Samples containing more than 14 per cent. have generally been strengthened by addition of rectified spirit. The author suggests a reduction of the standard. He also gives a series of tests, &c.:—

1. The specific gravity at 60° F. should be between 0.985 and 1.010.

2. The residue, when dried during 12 hours at 212° F., should be from 2 to 5 per cent. by weight.

3. 100 c.c. of the sample should require from 5 to 10 c.c. of normal potash solution for neutralisation (limit of free acid).

4. The wine should not contain more than 4 per cent. by weight of sugar.

5. It should yield by distillation, from 11 to 14 per cent. by weight of absolute alcohol.

6. Sherry wine should not contain citric or free tartaric acids, and should be entirely free from salicylic acid, formaldehyde, or other added preservative.—A. S.

Altered Wines, Proportion of Glycerin in. [Bitterness, &c.] J. Laborde. La Bière, 4, [11], 162—161.

The author has examined the amount of glycerin and its ratio to alcohol in various wines that have sustained alteration through bacterial or other agency. In the case of mannite wines he finds that the presence of mannite does not affect the alcohol-glycerin ratio, which remains at about the normal proportion of 12:1, mannite fermentation—which does not produce glycerol—only setting in, as a rule, when the alcoholic ferment is destroyed or paralysed before all the sugar has been attacked.

Mycoderma vini attacks both the alcohol and glycerin in wine, but in such proportion that their original ratio is finally unchanged; two samples, one infested with the mycoderma and the other free, having exhibited at the end of 12 months the ratios of 11.7 and 11.8 to 1 respectively, although at the outset the alcohol suffered to a greater extent than the glycerin. This was shown by an experiment with a liquid containing 10 c.c. of alcohol and 8 grms. of glycerol per litre, which, after two months' exposure at 25° in a Duclaux flask with aerating tubes, lost the whole of the alcohol, but only 2.8 grms. of glycerin.

Acid Wines.—*Mycoderma aceti* converts the alcohol into acetic acid without affecting the glycerin, but *bacterium xylinum* acts readily on both in presence of air, 5 per cent. of alcohol (converted into acetic acid) and 5 grms. of glycerin per litre being in 10 weeks' time reduced to nil and 0.75 gm. respectively.

In wines that lose their colour ("break") no change in the alcohol-glycerin ratio is apparent.

Turned Wines.—There are no certain indications of any action of the organism concerned in this malady on glycerin, the cause of the low proportion of this latter substance (about 1:16 of alcohol) found by Gayon and Dubourg being probably the inferiority of the must of wines subject to this form of sickness.

Bitter Wines.—A Médoc wine of 1887 vintage, employed by Gayon as a check sample in a pasteurising experiment, was examined by the author and found to exhibit the characteristics of bitter wine, having a pronounced bitter taste, a low percentage of volatile acids, and containing a number of rod-like organisms larger than those causing the wine to "turn." Whilst the amount of alcohol remained the same as in the pasteurised sample, the glycerin had decreased from 7.6 to 4.6 grms. per litre; the loss in this case is very similar to that found by Pasteur (3.4 grms.) in altered Burgundy. A similar loss of glycerin was observed in a Médoc, 1892, wine, part of which turned bitter in bottle. Judged by the flavour alone, the Gironde wines appear to be seldom subject to turning bitter; but since, if examined closely, other characteristics of this malady may be observed in altered wines, it may be, as suggested by Pasteur, that the organisms causing "turning" and bitterness are present together or in succession, and that to this circumstance the low proportion of glycerin in "turned" wines, is due.—C. S.

Beer, A Cause of Musty Taste in. W. Windisch. Wochenschr. für Brau. 1896, 13, 1177.

A raw, musty taste and odour is frequently imparted to beer by impure musty air in the cellar, and sometimes by the employment of old, spoilt, and even mouldy hops. The author has recently come across three cases of mustiness in beer which he has traced to another cause, namely, contamination with *bacterium termo*. The contamination occurred through the worts being left too long on the coolers. *Bacterium termo* thrives vigorously in wort, but perishes after the addition of the yeast. This source of mustiness may therefore be guarded against by shortening

as far as possible the time the wort remains on the cooler and by adding the yeast whilst the wort is running into the fermenting vessel.—A. K. M.

Acid in Potato Wort resulting from the Use of Diseased Tubers; An Excess of. G. Heinzelmann. Zeits. für Spiritusind. 1896, 353.

A DISTILLER who was using badly diseased potatoes obtained a very poor yield of alcohol owing to an excessive development of acid-producing bacteria in the wort. The author found that by adding a small amount of bi-sulphite of lime together with the yeast, he obtained a normal fermentation.—A. L. S.

Malt Extract for Colouring and Flavouring Beer; A Process for preparing a. J. F. Theurer. Ger. Pat. 88,319, 1896.

A MALT wort is prepared in the usual way and concentrated *in vacuo* to a syrup; it is then heated under pressure at a temperature of 115°–120° C. until the required colour and aroma are obtained.—A. L. S.

Lactic Acid in "Souring the Mash." J. Effront. Ann. Inst. Pasteur, Sept. 1896.

FROM his researches the author concludes that the value of the practice of lactic acidification of distillery wort is not due to the antiseptic properties of lactic acid, but rather to the physiological influence exerted on the yeast by the conditions (concentration, acidity, and low temperature) of the operation, whereby the activity of the yeast is increased at the expense of its reproductive power. The temperature (50°) employed in practice appears to result in the selection of a lactic ferment capable of resisting a high temperature and of giving a more rapid acidification with a minimum production of volatile acid.—C. S.

Carbohydrates, Easily and with difficulty fermentable. E. Prior. Bayerisches Brauer J. 1896, 6, 385–386.

THE author is of opinion that the end-products of the hydrolysis of starch by diastase consist of three achroodextrins and maltose, and that Lintner's isomaltose is a mixture of achroodextrin and maltose (Ling and Baker, this Journal, 1895, 175). Achroodextrins I. and II. were described by Lintner and Düll, whilst achroodextrin III., which immediately precedes maltose in a starch conversion, has been isolated and studied by the author. This body in a pure condition has a specific rotatory power of $[\alpha]_D^{20} 171^\circ$, a reducing power of 42.5 (maltose = 100), and a molecular weight favouring the formula $2(C_{12}H_{20}O_{10}) + H_2O$. Achroodextrins I. and II., though unaffected by most yeasts, are fermented by the high-fermentation yeast *Logos* and by *Schizosaccharomyces Pombe*. Experiments carried out under the usual conditions at 25° C. show that achroodextrin III. is partially fermented by Saaz and Froberg yeast, with Froberg to a greater extent than Saaz, and completely by *Logos* in an aqueous yeast extract. In the author's vacuum fermentation apparatus, Saaz and Froberg yeast completely fermented achroodextrin III. This dextrin is the constituent of wort fermentable with difficulty, which causes the differences in the end fermentation products when Saaz, Froberg, and *Logos* yeasts are used; this body has also the important influence on the degree of fermentation and after-fermentation which has hitherto been attributed to isomaltose.

The difficult fermentability of achroodextrin III. arises partly from the slight capability of diffusion as compared with the easily fermentable sugar, and partly from the circumstance that it is hydrated by yeast maltase to maltose, and finally to glucose, in order that it may be ready for fermentation.

The author's recent investigations upon worts which have been fermented by Saaz, Froberg, and *Logos* yeasts, show that maltose is present in the unfermentable portion in all three cases; in the first mentioned, glucose was found, which could only arise from enzyme action on the maltose.

—J. L. B.

Substitutes and Preservatives in American Breweries. Wochenschr. für Brau. 1896, 13, 1177–1179.

THIS is a report of a committee of the United States Brewers' Union on the replies received to a series of questions addressed to the members, concerning the materials which should be employed in the manufacture of beer. With regard to malt substitutes, the question as to whether it is advisable to manufacture beer solely from barley-malt, hops, water, and yeast, was answered in the affirmative only in two cases, and even one of these advocates of pure malt beer, states in another place that in order to produce a beer of greater stability, and having a pure, pleasant taste, it is advisable to use some raw grain, and that the public mostly prefer such beers. This last point is also emphasised by other brewers. With reference to the employment of malted wheat or maize, opinion appears to be about equally divided, but in some cases the question seems to have been assumed to refer to the complete substitution of these substances, which was not intended, and the objections raised only hold good where the quantities employed are excessive. On the other hand, the replies were, with only one exception, in favour of the use of unmalted grain, the majority of the brewers giving preference to rice and maize. The question as to whether raw-grain beers are objectionable from the hygienic point of view was also, with one exception, answered in the negative. With regard to the amount of raw grain recommended, this varies between 20 and 50 per cent. according to local conditions and the character of the beer to be produced, the majority of the brewers being in favour of 30–40 per cent. Opinion is more divided as to the use of grape-sugar, glucose, and syrup, but here again the majority are of opinion that when moderate quantities of pure preparations are used, the quality of the beer will not be affected.

With regard to hop substitutes, the use of any injurious preparations is denied. More than two-thirds of the brewers have never used hop substitutes, and where these have been partially employed, they have consisted of hop extract or lupulin obtained directly from hops, and containing as they do the essential constituents of the latter, these cannot be regarded as injurious substances.

The employment of preservatives is regarded with favour by the majority of the brewers, and in fact, during the hot weather, as necessary for the production of a good and stable beer.—A. K. M.

PATENTS.

Wort: Impts. in Boiling Wort and Extracting the Valuable Properties of the Hops, and Apparatus connected therewith. W. T. Ramsden, Middlesex. Eng. Pat. 20,176, Oct. 26, 1895.

THE wort is heated with the hops in a closed vessel, provided with some arrangement for keeping the wort and hops in circulation. When the desired temperature and pressure have been reached, sufficient heat is supplied to merely maintain these for the necessary length of time. The objects gained consist in saving the aroma due to the volatile constituents of the hops and in economising the fuel.—A. K. M.

Beer, Process for the Preservation of. [Adding Distillates from Strong Beer.] A. Lippke, Tilsit, Prussia. Eng. Pat. 17,183, Aug. 4, 1896.

THE process consists in distilling a strong beer and passing the distillate directly into the beer to be preserved. The amount of alcohol thus introduced should vary with the strength of the beer.—A. K. M.

Mashing and Brewing, An Improved Process and Apparatus for. L. Procházka, Turnau, Bohemia. Eng. Pat. 17,246, Aug. 4, 1896.

THIS is an improvement of the process described in Eng. Pat. 14,919, 1894 (this Journal, 1895, 981). The mash produced at any mashing temperature is allowed to settle, the clear diastatic malt extract is run off, the grains mash heated to 75°, and then boiled, whilst air at a temperature

of 125° is blown through for the purpose of peptonising and dissolving part of the albuminoid matter. The product is then mixed with the diastatic wort in order to saccharify the remaining starch, the whole is then boiled, the wort drawn off and hopped in the usual manner. The specification contains a full description of the apparatus employed.

—A. K. M.

Alcohol, Impts. in Check-Sampling and Measuring Apparatus for. [Use of Tipping Vessel and Gauged Catch Vessel.] L. Gelis, Toulouse, France. Eng. Pat. 20,235, Oct. 26, 1895.

The alcohol from the still runs into a tipping vessel suspended from a lever which is weighted by an adjustable counterpoise. When the tipping vessel discharges its contents, a small but definite proportion of the latter runs into a special reservoir of known capacity, and provided with a gauge so that the quantity can at any moment be measured, and its mean strength will correspond with that of the bulk. The apparatus is provided with four dials, indicating units to thousands, and the whole of the mechanism is actuated by the weight of the alcohol starting the tipping vessel.

—A. K. M.

Vinegar, Impts. in the Manufacture of. [Treating with Animal Charcoal.] F. G. Powell, A. Powell, M. E. W. Powell, and R. H. R. Powell, Bristol. Eng. Pat. 22,765, Nov. 28, 1895.

These improvements refer to the treatment of vinegar with animal charcoal, with the object of making it paler in colour or even colourless.—A. K. M.

Wine, Sparkling; Impts. in the Manufacture of [Addition of Sugar and Further Fermentation], and Apparatus therefor. A. Möller, Berlin. Eng. Pat. 14,501, June 30, 1896.

The apparatus consists of a bottle-shaped glass vessel of 200 or more litres capacity, and constructed to withstand pressure. It is provided with an exit tube reaching nearly to the bottom, and arranged so that no sediment settles in the latter. The vessel is charged with wine, to which some pure sugar candy is added, and the whole is allowed to ferment at a temperature of 16°–25°. In about a fortnight the carbonic acid produced will exert a pressure of about 5–6 atmospheres; the sediment will settle at the bottom and the wine will be bright. The vessel, with contents, is then kept in a cool place for 3–4 months for the wine to mature, after which it is drawn off into bottles, and is clear and brilliant. The pressure of the gas forces the wine out of the vessel as soon as the tap is turned on, but as the pressure diminishes as the wine is drawn off, artificial carbonic acid is forced in through a side tube in the neck of the apparatus. The vessel and outlet tube being made of glass, there is no fear of the wine acquiring any undesirable taste.—A. K. M.

XVIII.—FOODS; SANITATION, WATER PURIFICATION, & DISINFECTANTS.

(B).—SANITATION; WATER PURIFICATION.

Filtration of Sewage Effluents. First portion of a report made by Sir H. Roscoe to the Rivers Committee of the Manchester Corporation. Chem. Trade J., 19, 276–277 and 293.

Two experimental filters were constructed, one containing cinders and the other coke. The upper stratum of each filter was composed of clean-washed gravel, and the material composing the next layer was made to pass a 3-in. mesh but not a 1-in. mesh sieve. The filters were put into operation on Dec. 16th, 1895, and were supplied with the tank effluent from the Davyhulme Sewage Works, where lime and copperas are used as precipitants. From Dec. 15th, 1895, to Jan. 4th, 1896, each filter was emptied and filled once a day, and whilst resting full the water was level with the under surface of the gravel. Filtration took place at the rate of 63·7 galls. per square yard per 24 hours.

From Jan. 6th to Jan. 21st each filter was filled and emptied twice a day, increasing the rate of filtration to 122 galls. per square yard per 24 hours, and during this period the percentage reduction of organic impurity, as measured by the albuminoid ammonia, and the oxygen absorbed in 4 hours, averaged 47 per cent. in the cinder filtrate and 43 per cent. in the coke filtrate. Expressed as grains per gallon, the albuminoid ammonia was, in the—

	Tank Effluent. Cinder Filtrate. Coke Filtrate.		
Maximum	0·35	0·22	0·22
Minimum	0·07	0·025	0·027
Average	0·178	0·09	0·10

and the oxygen absorbed in 4 hours was—

Maximum	2·59	1·45	1·78
Minimum	1·00	0·59	0·58
Average	1·72	0·95	1·00

About half the time was taken up in filling, resting full, and emptying, and the remaining half in aerating the filters.

From Jan. 22nd to March 22nd the rate of filtration was further increased to an average of 171 galls. per square yard per 24 hours, and the daily analyses showed that cinder filtration removed, on an average, about 56 per cent., and coke filtration about 51 per cent. of the organic impurity remaining in the tank effluent. Detailed consideration of the nine weekly averages during this latter period showed that the albuminoid ammonia was in six cases above the limit of impurity which it is desirable should not be exceeded, and in three cases below the limit, in the case of both filters. The oxygen absorbed in 4 hours showed that in only one case was the weekly average above the limit with cinder filtration, the other eight averages being below the limit. The coke filtrate gave four weekly averages slightly above the limit, one decidedly above, and four below. (The limits are not stated.) The cinder filter therefore gave a better result than the coke filter. The chemical results further showed that, generally, the free ammonia was slightly higher in both filtrates than in the tank effluent, and the oxidised nitrogen lower. Thus, although a large oxidation of organic carbon took place, the organic nitrogen was not oxidised, but some nitrite and nitrate were reduced. The total purification effected is regarded as, upon the whole, satisfactory, but it is pointed out that the true aim of purification is the conversion of the organic nitrogen into nitrites and nitrates, and although this had not yet been attained in these filters it was believed that if the experiments had been continued for a longer period this, the main object of the experiments, might have been attained.

The analyses of the effluents from these filters, when compared with the effluents from the land filters which were working at the same time, show that so far as the chemical results are concerned, land filtration far exceeds the results of either cinder or coke filtration; but it is pointed out that the volume of effluent which can be treated permanently on land is limited as compared with the volume which can be filtered by artificial filters.

When the experiments were ended on March 22nd, the materials composing the coke and cinder filters were examined, and there was found to be some accumulation of both organic and inorganic matters throughout the filtering material. Samples placed in stoppered bottles and kept at a temperature favourable to secondary decomposition remained perfectly sweet, and only developed a slight earthy smell. Vegetable moulds appeared, and grains germinated in the material under these conditions.

Peroxide of iron contained in the cinder material was not reduced to a lower oxide, showing that the deposited matters did not appreciably absorb oxygen. To what extent foreign matters may accumulate in this kind of filters without crippling their working, time alone can determine.

In conclusion, it is recommended that an artificial area of cinder filters be constructed, which, under skilful management, ought to be able to deal with about 800,000 galls. of tank effluent per acre per day, the depth of filtering material

to be 3 ft. But it is insisted that the adoption of so large an area of filter beds is only advocated on the understanding that they are worked on the following principles, neglect of which may render them putrid and worse than useless, viz.:—

- 1st. Perfect aëration.
- 2nd. The equable distribution of the effluent over the whole surface of the filter bed, and downward filtration.
- 3rd. The retention of all suspended solids on the upper surface of the filter, which must from time to time be renewed.
- 4th. The free flow of the effluent from the bottom of the filter, drawing air into the pores of the material from the surface downwards.
- 5th. The volume of effluent water applied, not to exceed 800,000 galis. per acre per day.—L. A.

PATENTS.

Water, Improved Process and Apparatus for Purifying. [Automatic Addition of Oxidising Agents, followed by Filtration.] H. L. Doulton and R. Meldrum, Lambeth, Surrey. Eng. Pat. 22,132, Nov. 20, 1895.

THE process consists in adding to the water a soluble substance capable of oxidising organic matter, such as one of the various permanganates and manganates, and then filtering through a material such as charcoal, coke, or porous silica, capable of clarifying the water and at the same time removing from it the chemical reagent. A suitable domestic filter is described for carrying out this purifying process, with a device for automatically adding a suitable quantity of "oxidising material" before filtration.—L. A.

Sewage Matters or other Foul Waters, Impts. in the Production of Composition for Treating. [Nitric Cake roasted with Baucite, &c.] G. C. Kinloch and C. Heap, Rochdale. Eng. Pat. 20,355, Oct. 29, 1895.

NITRE cake is ground with shale, bauxite, clay, or any other suitable material containing alumina and iron, made into a paste with cold water or dilute sulphuric acid, moulded into bricks and allowed to set hard. During this setting process a chemical reaction occurs by which soluble aluminium and iron compounds are formed, and the product is used for purifying sewage.—L. A.

Sewage, Impts. in the Treatment of [Electrolysis of Chlorides], and in the Obtention of Valuable Products. James Hargreaves, Farnworth-in-Widnes, Lancaster. Eng. Pat. 23,064, Dec. 2, 1895.

A PLANT for electrolytically decomposing chlorides is erected in the immediate neighbourhood of a main outfall sewer. The chlorine is used to disinfect the sewage, whilst the metallic elements or hydroxides are obtained as marketable products. Further economy results from a combination of the above with an electric lighting plant, using the day current for electrolysis and the night current for lighting.—L. A.

(C.)—DISINFECTANTS.

Mercury Bichloride, New Application in Agriculture. [Germicide.] A. Lonay. Bull. de l'Assoc. Belge des Chimistes, 10, [7], 277—281.

DURING the last six years experiments have been carried on at Ciply with mercury bichloride solution as a preventive of the ravages of *Peronospora infestans* (potato disease). A 0.015 per cent. solution of the mercury salt is prepared, the liquid being coloured by 0.24 per cent. of copper sulphate. In this mixture the seed potatoes are steeped for about five minutes, and then thrown into heaps for planting. The results obtained are favourable; immunity from the disease being demonstrated. Moreover, the germination of the plants is accelerated, and the seed tubers are better preserved in the ground. Prolonged immersion (15 days) of the tubers in a solution of double the above strength did not retard germination.

For preserving the leaves of the growing plant from infection by the spores of *Peronospora*, the following mixture is found to be superior to Bouillie Bordelaise:—100 kilos. of quicklime are slaked with about one-third by

weight of water containing 200 grms. of copper sulphate per litre, the mixture being sprayed in the dry state over the plants at the rate of 250 kilos. per hectare, after the disease has become fully apparent in neighbouring fields. The powder adheres strongly to the leaves, and will withstand a week's rain.—C. S.

Disinfection of Large Apartments; Use of Formic Aldehyde Gas. E. Pfuhl. Zeits. für Hygiene, 1896, 339; also Proc. Inst. Civil Eng. 126 (iv.), 30—32.

METHYLIC alcohol was imperfectly burned in specially constructed lamps, with a capacity of about 200 c.c. each. Eight such lamps were used in a hospital-room containing 3.248 cb. ft.: and 5.4 grains of methylic alcohol were consumed per cubic foot of space. The larger apertures in the room were pasted up, and the vapours were allowed to remain in the room for about 20 hours. Test-objects, such as fresh and dry tuberculous sputa, and cultures of typhoid-, cholera-, diphtheria-, and other bacilli were spread about the room, the latter being either in the form of fresh agar cultivations or dried upon silk threads. Other experiments in smaller wards were tried, and one in a larger, but the last named was a failure. The lamps were not altogether satisfactory. But the author is of opinion that this gas cannot be used successfully for the disinfection of large spaces. Roux and Trillat have also been unsuccessful in using 8.8 pints of methylic alcohol in a Bardet-Trillat apparatus in a room containing 2,754 cb. ft.—W. G. M.

PATENTS.

Methyleneditannic Acids [Disinfectants], Improved Process for producing from Formaldehyde and Tannin. E. Dürkopff, Darmstadt, Germany. Eng. Pat. 816, Jan. 11, 1896.

THE process for the manufacture of methyleneditannic acids, which consists in adding a condensing agent, for example, concentrated hydrochloric acid, to a mixture of solutions of formaldehyde and a tannin, is claimed, and the products of such condensation, as new products.

—A. C. W.

Antiseptic Disinfectant. An Improved Manufacture of. [Hydroxyquinoline Potassium Sulphate.] A. J. Boulton, London. From F. Fritzsche and Co., Hamburg, Germany. Eng. Pat. 1409, Jan. 20, 1896.

TWO equivalents of o-hydroxyquinoline dissolved in alcohol are boiled with one equivalent of potassium or sodium pyrosulphate ($M_2S_2O_7$), and the crystalline product is dried and pressed. It is not hygroscopic, like the product made by the action of sulphuric acid, and it can be readily moulded into pastilles. It has no smell, and is neither irritating nor poisonous, yet it is a much more powerful disinfectant than phenol. It is soluble in water, and the solution has a remarkable power of dissolving phenols such as cresol and resorcinol.—L. A.

Disinfectant or Composition for Antiseptic, Disinfecting, Sanitary, and other Purposes; The Manufacture of an Improved. H. Hiscott, London. Eng. Pat. 20,246, Sept. 12, 1896.

COMMERCIAL "carbolic acid" is mixed with from one-half to nearly its whole weight of melted rosin, and to the mixture is added a sufficiency of strong alkali solution, with, if necessary, from 4 to 8 per cent. of cotton-seed oil or coconut oil soap to assist solution. The improvement consists in adding to this preparation α -naphthol, in the proportion of from $\frac{1}{2}$ lb. to 2 lb. for every 100 lb. of soluble phenols in the mixture.—L. A.

Sheep-Dip Powder, Impts. in. W. O., T. O., O., and W. B. B. Quibell, Newark, Nottingham. Eng. Pat. 20,702, Sept. 19, 1896.

FOR the preparation of a more or less dry compound which will not set hard by pressure or lapse of time, the inventors mix together arsenic, preferably rendered soluble with an alkali, sulphur, and an oily material, such as "spirits of

tar" (obtained from wood tar), rosin oil, or creosote oil. They prefer to use 100 parts of sulphur, 30 parts of arsenic, and about 5 parts of the fraction obtained from wood tar, having a specific gravity of about 0.874, 85 per cent. of which distils between 155° and 185° C.—L. A.

XIX.—PAPER, PASTEBOARD, Etc.

Paper in Sweden, Wood Supply for. Papier Zeit. 21, [95], 3102.

IN consequence of the unusual briskness in the Swedish iron and steel industry, there has been an increased demand for wood charcoal, so that the competition of the charcoal burners, who use the same kind of woods as the paper-pulp makers, has raised the price of the raw material for the latter product some 25 to 30 per cent., a rise out of all proportion to the increased rates obtainable for pulp. In view of the serious injuries sustained by the trade in 1895, makers are advised to combine to settle the price of pulp.

—C. S.

Resin-Sizing. Papier Zeit. 1896, 2883.

THE following method is given for preparing resin size :—To convert 500 kilos. of resin, dissolve 56 kilos. of soda-ash in 70 litres of water, and with this solution boil 400 kilos. of resin, added gradually. When dissolved, add the remaining 100 kilos. of resin in the form of a fine powder, after which continue to boil three hours.—C. F. C.

Blanc Fixe, Preparation of. Papier Zeit. 1896, 2883.

INSTRUCTIONS are given for the preparation of a sufficiently pure barium chloride from crude barium sulphide. The sulphide is decomposed by hydrochloric acid in slight excess, and is then boiled to expel sulphuretted hydrogen. The excess of acid is then neutralised with a further addition of barium sulphide. In this way the iron and other metals are precipitated. The precipitation of the sulphate, or blanc fixe, is carried out in 10 per cent. solution of BaCl₂, to which sulphuric acid of 20° B. is added with continual stirring.—C. F. C.

PATENTS.

Paper-Making Machinery, Impts. in Separating Fibres from the Waste Liquors of. T. A. Marshall, London. From G. Smidth, Copenhagen. Eng. Pat. 21,275, Dec. 18, 1895.

DESCRIBES an arrangement of tanks with wire gauze strainers for recovering the waste fibre carried away by the back-water of paper works.—L. A.

Paper, Leather, or other Fabric, or the Like, Coated with Adhesive Material; An Improved Manufacture of. E. A. Zuber, Rixheim, Alsace, Germany. Eng. Pat. 21,637, Dec. 23, 1895.

SIZE-COATED papers or fabrics as at present manufactured, are coated with a uniform smooth layer of adhesive material. The improvement consists in producing a rough layer, by constructing the cylinder, by means of which the material is coated, with a surface full of small cavities, so that the adhesive film is formed of an infinite number of small reliefs or projections connected by a thinner film. Paper sized in this way is very pliable, not breakable, and adheres easily if slightly wetted, qualities which render it serviceable for many purposes for which the paper at present made is useless or unsuitable.—L. A.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES AND EXTRACTS.

Indian Podophyllum. W. R. Dunstan, Scient. and Tech. Research Dept. Imp. Inst. J., Dec. 1896, 441.

A COMPLETE examination is now being conducted in the laboratories of the Scientific and Technical Department, of the constituents of the Indian plant, *podophyllum emodi*, with the object of ascertaining how far its constituents

resemble those of the well-known American drug, *podophyllum peltatum*, from which the resin called "podophyllin" is obtained, which is largely employed in medicine in this and other countries.

The resin "podophyllin" was first prepared from the Indian root (rhizome) by the process of the British Pharmacopœia, which consists in exhausting the drug by percolation with alcohol, concentrating the percolate, and precipitating the resin by the addition of water. The resin so obtained is washed with water and dried by exposure to the air. The "podophyllin" is much lighter in colour than that made from *podophyllum peltatum*; this was found to be due to the large quantity of the colourless crystalline substance "podophyllotoxin" which it contains (30 per cent.), while the commercial American resin contains on an average about 20 per cent.

Dr. Mackenzie finds that the two resins (Indian and American) are identical in their medicinal effects, and that, therefore, there is no reason why the resin obtained from the Indian root should not be substituted for the American resin.

This is an important result, since the Indian root contains from two to three times as much of the valuable resin as the American root, and, is therefore, the more satisfactory source of the resin.

The following is a tabular statement embodying the results of estimations of the resin in the American plant, and in several specimens of Indian drug collected in various localities :—

(a.) *Podophyllum emodi*—

Name of District in India yielding the Root.	Percentage of Resin found.
Kulu	9.55
Bashahr	9.003
*Chamba	11.12
† "	12.03
Hazara	9.06

* Young roots.

† Old roots.

(b.) *Podophyllum peltatum*—

Four commercial specimens of roots gave—

- | | |
|--------------------|-------------------|
| (1) 4.17 per cent. | (3) 5.4 per cent. |
| (2) 5.2 per cent. | (4) 5.2 per cent. |

Scopolamine and i-Scopolamine. O. Hesse. Ber. 1896, 29, 2439.

A REPLY to the paper by Schmidt (this Journal, 1896, 613 and 737). The author finds that alkalis do not change the rotatory power of pure scopolamine (hyoscyne), and supposes that Schmidt must have used the commercial hydrobromide, since in Arch. der Pharm. 232, 395, the latter states that hydrobromide of i-scopolamine is very different to ordinary scopolamine hydrobromide, whilst in the former paper they were stated to be identical in appearance. From pure hyoscyne hydrobromide the author obtained no inactive scopolamine, but from the ordinary salt he obtained a substance in every respect similar to Schmidt's i-scopolamine hydrobromide, and this body after repeated recrystallisation yielded a considerable quantity of atropine hydrobromide. To the presence of this salt the difference in rotatory power of the different preparations is due.—A. C. W.

Camphor-Distilling from Leaves. D. Hooper. Chem. and Druggist, 1896, 59, 796.

THE author distilled two samples of leaves from camphor trees, in the ordinary way, for six hours. The first sample was a 50 lb. batch of fresh leaves from a camphor tree growing in the Government gardens at Ootacamund, Madras. They yielded 1 per cent. of essential oil of a pale yellow colour, and showing the following constants :—Sp. gr. at 15° C., 0.9322; optical rotation, + 9°·4 in a 200-mm. tube. Fractionation began at 175° C., with the following results :—Below 180° C., 20.6 per cent.; 180° to 185° C., 31.0 per cent.; 185° to 190° C., 15.5 per cent.; 190° to 195° C., 10.6 per cent.; 195° to 200° C., 5.6 per cent.; 200° to 205° C., 3.3 per cent.; residue, 8.6 per cent.;

total, 95.2 per cent. The loss was accounted for by the congelation of some of the oil in the condenser. The residual matter in the retort had a yellowish colour, a marked camphoraceous odour, and was solid at the ordinary temperature. The second sample was obtained from Naduvattam, in the Nilgiris, and the trees that yielded it were younger than those at Ootacamund, and grown at more than 1,000 feet less elevation. With this sample, the worm of the still was almost choked by the large quantity of camphor that condensed in it. About 4 fl. oz. of oil, containing suspended crystalline matter, was collected; after straining through cloth and pressing, the solid matter was recovered as a cake of camphor weighing 2 oz. The clear oil had a sp. gr. of 0.9314 at 15° C., and an optical rotation of + 54° in a 200-mm. tube. Fractionation began at 165° C., with the following results:—Below 185° C., 13.3 per cent.; 185° to 190° C., 20 per cent.; 190° to 195° C., 15.5 per cent.; 195° to 200° C., 20 per cent.; residue, 25 per cent. The oil from the Naduvattam leaves contained a total of 75 per cent. of camphor, soluble in rectified spirit, and having optical rotation, + 30°.—A. S.

Orycamphor. Manasse. Pharm. Zeit. **41**, 696.

A product of the oxidation of ordinary camphor, and recommended for relieving difficulty of respiration. It is soluble in water and is stated to have the composition represented by the formula $\text{C}_{10}\text{H}_{14}\text{O}_2$.—A. S.

Essential Oils. Duyk. J. Pharm. Chim. 1896, **4**, 453.

A CONTINUATION of articles abstracted in this Journal, 1896, 739 and 826.

Linalool Essence.—This is also called, according to its source, Rhodes wood oil, rose oil, and essence of *Licari Kandli*. The essence contains linalyl alcohol, an isomer of geraniol, converted by gentle oxidation into linal, identical with citral. On saponifying linalyl acetate a stereo-isomer, linalhodol, is obtained. Linalol is somewhat levo-rotatory; it boils at 97° C. under 15 mm. pressure, and at 20° C. has the density 0.867.

Oil of Lavender.—1 kilo. of the dry flowers of *lavandula vera* produces 3–6 grms. of the oil. Recently distilled the oil has an acid reaction, which is lost on keeping. The rotation, -8° , serves to distinguish this oil from the almost inactive oil of spike lavender, the latter also contains a much smaller amount of volatile acid. The oil contains large quantities of borneol, linalol, both free and in the form of acetic, butyric, valeric, &c., esters, cineol, and sesquiterpenes. On cooling no stearoptene is deposited. The French oil contains 30–40 per cent. of linalyl compounds, but the higher-priced Mitcham oil only 8–10 per cent. Generally, lavender oil is to be considered pure if it is soluble in three times its volume of 70 per cent. alcohol, and in the Abbé-Zeiss refractometer shows a refraction of 40° – 50° .

Oil of Spike Lavender contains, besides linalol and linalyl esters, much cineol and some camphor, also traces of geraniol, terpineol, and pinene. It is slightly dextro-rotatory and has an index of refraction of 1.4659.

Oil of Orange.—The essential oil of bitter orange, *citrus bigaradia*, is of higher value than that of the sweet orange, *citrus aurantium*. An oil of good quality, has the density of 0.8508 at 20°, and a rotation of $+92^\circ$. These oils are almost entirely composed of hydrocarbons, similar to limonene, and of small quantities of auranliol (linalol).

Oil of Petit Grain is obtained by the distillation of the young shoots and unripe fruits of *citrus aurantium* and *bigaradia*. The French oil is of better quality than the Paraguay; both contain linalol. The density of a good sample is 0.894–0.900 (Schimmel).—A. C. W.

Hazeline: Does it contain Formaldehyde? A. Gunn. Chem. and Druggist, 1896, **59**, 796.

THE author states that "hazeline" (distilled extract of witch-hazel) has an odour resembling that of a weak aqueous solution of formalin, and that it gives the formalin reaction by Helmer's test. The distillate from hazeline

made alkaline by potash solution, was declared to be formalin by several chemists, to whom it was submitted without mentioning the source.—A. S.

Chloroform. Pharm. Centralh. **37**, 715; Pharm. J. 1896, **57**, 377.

A new method of preparation consists in acting upon carbon tetrachloride with zinc and hydrochloric acid. Chlorine is replaced by hydrogen, and the hydrochloric acid formed acts upon the zinc with liberation of hydrogen, by which a further quantity of tetrachloride is reduced to chloroform. When there is no further formation of hydrochloric acid, the liquid is allowed to cool, and the layer of chloroform separated from the solution of zinc chloride.

—A. S.

Mydrol. [Iodo-methylphenylpyrazolone, *Febrifuge*.] Barbiano. Pharm. Centr. **37**, 718; Pharm. J. 1896, **57**, 378.

THIS name is given to the iodo-methylphenylpyrazolone. It is a white inodorous powder of bitter taste, freely soluble in water or alcohol, and insoluble in ether. It reduces the pulse and causes dilation of the pupil, and is stated to be non-poisonous.—A. S.

Action of Light on Amyl Alcohol. A. Richardson and E. C. Fortey. Proc. Chem. Soc. 1896, [169], 164–165.

IT was found that whereas in the case of methyl, ethyl, propyl, and butyl alcohols, an exposure extending over many months failed to produce any apparent change, the alcohols remaining neutral to litmus and containing no hydrogen peroxide, amyl alcohol gave strongly acid reactions and contained large quantities of hydrogen peroxide after only a few days' exposure. A similar change seemed to take place in the case of octyl alcohol, but to a very much smaller extent. The action of light on amyl alcohol was therefore studied in detail.

Amyl alcohol was exposed to light in presence of excess of water and of oxygen for a few days. A portion of the water was then tested with titanous acid, when the presence of hydrogen peroxide was shown by a deep brown coloration. Another portion was shaken with pure ether and potassium bichromate, when the ether assumed an intensely blue colour, leaving no doubt as to the presence of hydrogen peroxide in the solution. In another experiment liquid water was absent, amyl alcohol being exposed in presence of moist oxygen. Two days' exposure sufficed to bring about the formation of hydrogen peroxide, as shown by the titanous acid test. A third experiment was made with dry alcohol. A sample of amyl alcohol dried first from quicklime, then by distillation from sodium, was sealed in a bent tube containing oxygen and phosphorus pentoxide (care being taken not to allow the liquid to wet the pentoxide), and kept in the dark for seven weeks. After exposure the alcohol was found to contain abundance of hydrogen peroxide.

The acidity was found to be due to the presence of valerician acid, and the absence of carbon dioxide leads to the conclusion that the change is one of a comparatively simple nature, not involving the breaking down of the molecule. It seems, then, that the products formed by the oxidation of amyl alcohol in presence of sunlight and oxygen only differ from those formed when other oxidising agents are used in that hydrogen peroxide is formed instead of water. The change may, therefore, be represented by the following equation:—

It was found that the presence of sunlight was essential to the change, a sample of amyl alcohol kept in the dark at 100° for nine days remaining neutral to litmus and containing no hydrogen peroxide.

Ether, Action of Light on. A. Richardson and E. C. Fortey. Proc. Chem. Soc. 1896, [169], 165–166.

ETHER prepared from pure alcohol and pure sulphuric acid, and then treated with potassium bichromate, was dried by repeated distillation from phosphorus pentoxide in a specially constructed apparatus by means of which samples

could be sealed for use without contact with air. The ether was then exposed in a tube containing oxygen which had been dried by contact with phosphorus pentoxide for many weeks. After three days' exposure the liquid gave a well marked peroxide reaction when tested with titanous acid.

In order to investigate the other products formed, a sample of ether was exposed for many weeks in presence of water and oxygen. It was then rich in hydrogen peroxide, and gave an acid reaction with litmus. The neutralised solution was distilled on the water-bath. The distillate, consisting chiefly of ether, was also proved to contain aldehyde by its reducing action on ammoniacal silver nitrate, and by its restoring the colour to rosaniline hydrochloride, decolorised by sulphurous acid. The residue in the distilling flask gave a distinct red colour with ferric chloride and the characteristic smell of ethyl acetate on warming with alcohol and sulphuric acid, leaving no doubt as to the formation of acetic acid. No carbon dioxide was formed in the reaction, which may, therefore, probably be represented by the equation—

aldehyde being an intermediate product. Here, again, hydrogen peroxide takes the place of the water which is formed when ordinary oxidising agents are used.

PATENTS.

Paranitrophenol and Homologous Ethers, and Ortho-nitrotoluene Parasulphonic Acid, Impts. in the Production of. La Société Chimique des Usines du Rhone, anct. Gilliard, P. Monet, and Cartier, Lyons, France. Eng. Pat. 21,194, Dec. 17, 1895.

The nitration of phenol produces varying amounts of *o*- and *p*-nitrophenols. According to the claims of this patent, phenol is combined with an aromatic sulphonic chloride, toluene sulphonic chloride by preference,

on nitration of the product, the *p*-nitrophenol ester of *o*-nitrotoluene-*p*-sulphonic acid is formed.

The nitration is performed by mixing the phenol sulphonic ester with potassium nitrate or concentrated nitric acid and adding in small quantities to sulphuric acid (66 B.), the

temperature being kept at 15° C. The nitrated ester is split up into *p*-nitrophenol and *o*-nitrotoluene-*p*-sulphonic acid by boiling with solution of sodium or caustic soda or potash in absolute alcohol, and after distilling off alcohol, distilling off the *p*-nitrophenol in a current of steam. From the residue, *o*-nitro-*p*-toluene sulphonic acid is precipitated by mineral acids.—A. C. W.

Hydroxy-Phenacetine-Salicylate, Manufacture of. O. Imray, London.—From Farbwerke, vorm. Meister, Lucius, and Brünig, Hoechst am Main, Germany. Eng. Pat. 24,517, Dec. 21, 1895.

HYDROXYPHENACETIN SALICYLATE is claimed as a new product, together with its process of manufacture by heating chloro- or bromo-phenacetin with sodium or other salicylates. The condensation takes place on heating for half an hour at 170–180° C.

—A. C. W.

Saccharine, or Compounds thereof, or Mixtures containing the same, Impts. in the Manufacture of, and in the Production and Treatment of Materials for Use therein. C. Fahlberg, Salbke Westerhüsen, Germany. Eng. Pat. 17,101, Aug. 6, 1896.

In Eng. Pat. 10,955, 1895 (this Journal, 1896, 49), the separation of ortho- and paratoluene sulphonic acids by means of the magnesium salts was claimed. According to the present patent, the zinc salts may be used in the same process.—A. C. W.

XXI.—PHOTOGRAPHY.

Aldehydes and Acetones in Presence of Sodium Sulphite, Use of, in Photographic Development. Lumière Bros. and Seyewetz. Bull. Soc. Chim. 1896, 15, 1161.

It has been known for some time (cf. this Journal, 1890, 101) that the addition of formaldehyde to an organic developer considerably increases its power; but the mechanism of the reaction has not hitherto been discovered. The present authors find that most aldehydes and acetones have the same effect, even causing phenolic developers to act on the latent image without the assistance of any alkali; but the phenomenon is only to be observed in the presence of sodium sulphite. From a number of experiments it would seem probable that a decomposition of the subjoined nature must take place to a certain extent, proceeding during the operation of development—

and that the alkaline phenate so produced does the work of the alkali usually employed. It has not been found possible, however, to isolate the latter compound; but on evaporating a mixture composed as above, or containing pyrogallol instead of the quinol (hydroquinone), thoroughly drying the crystals, and boiling them with excess of alkali, a small quantity of acetone was set free, while in the absence of the phenol a negative result was obtained. Moreover, the presence of acetone causes ether to extract from the mixture a smaller amount of the phenolic body than would otherwise be the case, which appears to show that it is partly retained in the form of an alkaline salt.

From the practical point of view the authors find that acetone works best with "pyro"; and that in the case of hydroquinone (quinol) variations in the amount of sulphite employed make little difference to the result, whilst within certain limits the developing power increases with the quantity of acetone. The following formula is suggested:—hydroquinone (quinol), 3 grms.; sodium sulphite, 10; acetone, 10 c.c.; water, 100.—F. H. L.

XXII.—EXPLOSIVES, MATCHES, Etc.

PATENTS.

Explosives containing Saltpetre. Process for the Manufacture of. M. Bielefeldt, Wittenberg, Saxony. Eng. Pat. 17,204, Aug. 4, 1896.

AN explosive, composed of sodium and potassium nitrates, sulphur, coal-tar (or, in place, or partly in place of the latter, resins, fatty drying oils, lacs, and varnishes), and potassium bichromate, permanganates, and manganates.

The following is given as a suitable composition:—Soda saltpetre, 69 per cent.; potash saltpetre, 5 per cent.; sulphur, 10 per cent.; coal-tar, 15 per cent.; potassium bichromate, 1 per cent.

The comminuted ingredients are thoroughly mixed together and subsequently compressed between heated plates or rollers. When the pressure applied is sufficiently great the simultaneous heating may be omitted, particularly if the mixed ingredients have been moistened, or if adhesive agents have been added. The coherent mass obtained in this manner may be finally treated in any desired manner.—R. B. P.

Phosphorus, its Acids and Salts; Impts. relating to the Production of, from Mineral Phosphates, Bones, and other Materials containing Phosphoric Acid. [Heating in Electric Furnace with Carbon.] H. Hilbert, Biebrich-on-the-Rhine, and A. Frank, Charlottenburg, Germany. Eng. Pat. 18,785, Oct. 7, 1895.

ORDINARY tricalcium phosphate is mixed with carbon, and heated intensely, as in an electric furnace, to form calcium carbide and set free phosphorus, arrangements for collecting which are made. The proportions to be used are indicated by the equation—

Aluminium phosphate may be similarly treated, the proportions being—

Mineral phosphates generally, bones, and phosphatic slags, may be used instead of a pure phosphate.—E. S.

XXIII.—ANALYTICAL CHEMISTRY.

APPARATUS, ETC.

Potash Bulb, A New Form of. M. Gomberg. J. Amer. Chem. Soc. 18, [11], 941–942.

IN the diagram, compartments B and C together contain as much of the strong potash solution as would completely fill

A, the latter serving as a safety reservoir in case of back-suction. D, which is fastened to the bulb by means of a ground-glass joint, contains solid caustic potash, or soda lime, supported by a plug of glass wool.—H. B.

PATENTS.

Butyrometers or like Fat-Testing Instruments, Impts. in or relating to. N. Gerber, Zürich. Eng. Pat. 18,282, Aug. 18, 1896.

THE neck of the butyrometer is made cylindrical in form, and is provided with one or more annular grooves. The india-rubber plug used to close the instrument at the bottom is of a cylindrical shape, and fits firmly into these grooves, so that there is less danger of the plug being blown out of the apparatus by the gases formed in the butyrometer by the action of the sulphuric acid on the milk or other substances under examination.—W. P. S.

Thermometers [Maximum and Minimum Upright], Impts. in. J. J. Hicks, Hatton Garden, London. Eng. Pat. 23,300, Dec. 5, 1895.

MAXIMUM and minimum thermometers are formed of vertical tubes having a thermometric bulb at the lower end and an expansion chamber at the upper. They contain a short length of mercury, say, from $\frac{1}{2}$ to $\frac{1}{4}$ in., a dense thermometric fluid, as creosote or sulphuric acid, and maximum and minimum indexes, which are set by a magnet in the usual manner. In another form, the vertical tube is connected at the top to a second tube parallel thereto, having an expansion chamber at its lower end. Both tubes are provided with recording indexes.—R. S.

INORGANIC CHEMISTRY.—
QUANTITATIVE.

Pettenkofer's Method for Determining Carbonic Anhydride in Air. Prof. Letts and R. F. Blake. Proc. Chem. Soc. 1896, [169], 192–193.

THE authors discuss the errors in the process of absorbing the carbonic anhydride by baryta from a sample of air collected in a glass vessel, and titrating with acid, and show that, in addition to the more obvious sources of error, the action of the alkaline absorbent on the glass is one of importance.

In order to avoid it, they coat both the receiver containing the air sample and the bottle holding the stock of standard solution of baryta with paraffin wax. By this means they at once obtained more concordant results in a series of determinations. They then proceeded to test the degree, both of accuracy and of delicacy, of Pettenkofer's process if carried out with all the available precautions which suggested themselves. For this purpose they employed paraffined receiving vessels, an apparatus for performing the titrations in a vacuum, and burettes of special construction. In addition, an apparatus was used for delivering very accurately measured volumes of pure carbonic anhydride into known volumes of air previously freed from that gas.

Experimenting with such mixtures of the two as occur in air, containing about 3 vols. of carbonic anhydride in 10,000, the authors show that with careful work the mean error in the determinations need not exceed -0.04 part. The actual quantity of carbonic anhydride added to each receiver full of air, in a series of five experiments, amounted to 0.927 c.c.; the mean amount, found to be 0.916 c.c., giving, therefore, a mean error of -0.011 c.c.

They thus show that Pettenkofer's process, if suitably performed, is one of great accuracy and delicacy.

Purifying Material [Gas Works], Testing the Regeneration of. Leybold. J. de l'Eclair. au Gaz, 44, [21], 407–409.

TWO methods, one direct the other indirect, of determining the degree of regeneration attained by the hydroxide of iron in the purifying material when exposed to the air in heaps, are proposed by the author. The first consists in measuring the volume of hydrogen sulphide evolved from a constant weight or volume of the substance under the action of nitric acid in an apparatus resembling Knop's nitrometer, and is performed as follows:—About 25 grms. of substance are placed in a small glass inserted in a wide-mouthed bottle, standing up to its neck in cold water, and containing some 50 c.c. of nitric acid of 20° B., diluted with an equal volume

of water. The caoutchouc stopper of the bottle is connected, by means of a tapped glass tube and caoutchouc tubing, with the upper extremity of a gas-testing tube, graduated from 0 to 500 c.c., which is immersed up to the zero mark in water. On tilting the bottle, the acid and substance are brought into contact, and the hydrogen sulphide rapidly given off, acts by downward displacement of air upon the surface of the water in the graduated tube. The amount of depression of the water column thus represents the volume of H_2S evolved. This operation is repeated after each turning of the heap, until all the iron sulphide is found to be oxidised. The samples should always be taken from the bottom of the heap, or the results will not afford correct indications of the progress of the regeneration.

The indirect method is performed by collecting samples of the gas given off by the heap by means of a lead pipe inserted into the bottom of the mass, the contents of the pipe being then tested for the proportion of oxygen present. When this has reached its maximum, or even when it attains 16 per cent., the regeneration will be complete.

—C. S.

ORGANIC CHEMISTRY.—QUALITATIVE.

Benzenesulphinic Acid, A New Reagent. [Presence of Quinone and Quinonoid Groups.] O. Hinsberg and A. Himmelschein. Ber. 1896, 29, 2019—2023.

HINSBERG has shown (Ber. 27, 3259; 28, 1315; 29, 785) that benzenesulphinic acid combines with quinones and quinone-imides of the benzene and naphthalene series, forming derivatives of diphenylsulphone and phenyl-naphthylsulphone. The condition for the reaction is the presence in the molecule of the quinone or quinone-imide of a free hydrogen atom in an *o*- or *p*-position to one of the CO or $\text{C}:\text{NH}$ groups and the absence from the rings of hydroxyl- and amido-groups.

Phenazine reacts with benzenesulphinic acid, giving phenazylphenylsulphone—

a compound crystallising in pale yellow plates, m.p. 241°, and sparingly soluble in water and alcohol, but moderately soluble in acetic acid. It dissolves in concentrated sulphuric acid, with an orange colour, apparently forming with the acid a salt which is dissociated by water, as on the addition of the latter the free sulphone is precipitated. Alkalis at 100° have no action upon the compound, but zinc and hydrochloric acid, when heated with it, decompose it.

Its formation thus affords evidence of the quinonoid nature of phenazine.

The quinonoid condensation-derivative of *p*-amidobenzylalcohol, $\text{HN}:\text{C}_6\text{H}_4:\text{CH}_2$, obtained by heating this compound with dilute hydrochloric acid (O. and G. Fischer, Ber. 28, 881), reacts with benzenesulphinic acid with the formation of *amidotolylphenylsulphone*, $\text{C}_6\text{H}_5\text{NH}_2\text{CH}_2\text{SO}_2\text{C}_6\text{H}_4$. This forms yellow needles, m.p. 176°, is moderately soluble in hot water, and, on cooling, separates in colourless needles, which turn yellow on drying, owing, no doubt, to the loss of water of hydration. It combines with concentrated hydrochloric acid, giving a colourless salt, which is dissociated by water, dissolves in acetic acid with a yellow colour, and yields diazo-salts and azo-derivatives.—E. B.

Formula, Test for. Lebbin. Pharm. Zeit. 41, 681.

To a few cubic centimetres of a solution containing formic aldehyde, add about 0.05 gram. of resorcinol and an equal volume of caustic soda solution (50 per cent.), and heat the mixture to boiling. The yellowish colour first formed becomes red, and is permanent. This reaction does not appear to take place with other bodies besides formaldehyde, and is stated to be capable of detecting 1 part of formaldehyde in 10,000,000 parts of water. In the proportion of one millionth, the indication is very marked, and a volumetric method of quantitative determination may be adopted.—A. S.

Acid Magenta and Schiff's Reaction. L. Lefèvre. Bull. Soc. Chim. 1896, 15, 1169.

CAZENÈVE is in error when stating (Bull. Soc. Chim. 1896, 723; also this Journal, 1896, 560) that magenta S. does not yield the violet colour produced by rosaniline hydrochloride when its solution, decolorised by sulphurous acid, is mixed with aldehydes. The only difference is that the reaction is not instantaneous. Under certain abnormal conditions, the sulphonated compound may not give the reaction, but it will appear on addition of more aldehyde; just as it is possible, by adding three or four times the proper amount of bisulphite, to prevent the colour from being produced in the case of magenta itself. The nature of the aldehyde employed, also affects the rapidity of the test.

Schiff himself pointed out that his reaction did not depend on a simple regeneration of the magenta decolorised by the sulphurous acid, but on the formation of a new compound.

—F. H. L.

ORGANIC CHEMISTRY.—QUANTITATIVE.

Mineral Oils: Estimation of Gas-producing Value.

F. Helfers. Zeits. f. ang. Chem. 1896, 650—654.

The method of estimating the value of a gas-oil by its colour, specific gravity, creosote percentage, and boiling point is unsatisfactory, and the only reliable process is to measure the quantity and quality of the gas yielded by a given amount of the oil. As carried out at the various experimental stations a large and costly apparatus requiring for each experiment, from 10 to 150 kilos. of oil, is employed. This is quite unsuitable for small works, and for their purpose the author gives the results of his experiments with the Wertheke laboratory gasifying apparatus, and shows that by working with 40 grms. of the oil correct values may be obtained.

The required data are the amount of residue, tarry distillate, and the quantity and photometric value of the gas obtained on destructively distilling a given weight of the oil. The apparatus consists of (a.) A reservoir for the oil. (b.) A retort capable of being heated to, and maintained at, a constant high temperature. (c.) A condenser in which the tar is collected. (d.) A gasometer to receive the gas. These parts are separable from each other, and (a.), (b.), and (c.) are weighed before and after each experiment.

The normal course of the distillation is judged and regulated by the colour of the gas and gas-tar formed, which should be brown and dark-coloured respectively. A too rapid addition of oil to the retorts gives a white gas and a pale-brown tar, whereas, should the rate be too slow, the gas becomes dark brown and the tar very thick. The flow should be kept steady during the experiment, and may vary from 10 to 30 drops per minute according to the nature of the oil investigated.

The values obtained are calculated to 100 kilos. of the oil; according to Hirzel's formula the lighting value = $\text{Yield of gas} \times \text{photometric value} \times 1.00$ where the 35 stands

for an hourly consumption of 35 litres. Now different conditions of experiment may give from 100 kilos. of oil, in one case 50, and in a second trial 60 litres of gas, leading to a 50 per cent. less value for the lighting power in the second than in the first case. The author overcomes the deficiencies of this formula by the following considerations. He finds with an hourly consumption of 35 litres, and employing the German standard candle as the photometric standard, that the increase or decrease of the light strength (Z) bears the same ratio to the difference between the obtained (A) and the assumed average gas volume (50 cb. m.) as the oil residue, coke + tar (C + T), bears to 100 parts by weight of the oil.

$$Z : (A - 50) = (C + T) : 100$$

$$\text{or } Z = (A - 50) (C + T) / 100$$

Now $I_{50} = L + Z$, where L is the observed photometric value, and I_{50} this value calculated to a gas yield of 50 cb. m. Therefore—

$$I_{50} = L + (A - 50) (C + T) / 100$$

The following table shows the value of the method and how far this formula leads to correct results:—

	Analysts.									
	Heurici.	Diamant.		Eisenlohr.						Helfers.
		1.	2.	1.	2.	3.	4.	5.	6.	
Gas yield in cb.m. per 100 kilos. of oil.	55.70	63.36	54.23	58.90	54.72	59.09	61.10	48.55	54.93	57.17
Light value in German standard candles.	9.00	5.59	9.50	7.30	9.50	6.60	6.50	12.00	9.20	8.25
Coke, per 100 kilos. of oil	7.37	9.64	5.51	8.70	5.15	9.20	9.56	3.84	5.85	6.69
Tar, " " "	11.83	35.15	41.63	37.60	39.95	40.11	36.38	42.88	38.07	40.60
L ₂₀	11.46	11.48	11.54	11.42	11.62	11.08	11.59	11.40	11.35	11.64

The experimental gas yield should, for correct results, not be allowed to fall below 45 cb. m., or to rise above 70—75 cb. m. per 100 kilos. of oil. In measuring the gas, no pressure correction is necessary; reduction to normal temperature may be avoided by always working at about 20° C., the difference in value obtained between the limits of 17°—23° C. correspond to about half a candle.

The author shows that the errors due to oxidation of the retort and incomplete condensation of the tar, are small and tend to balance each other.

A comparison between the laboratory results and those obtained at the investigation stations with two different oils and calculated to 100 kilos., is shown below:—

	Station A.		Station B.	Laboratory Apparatus.	
	1.	2.		1.	2.
Gas yield	52.00	53.00	60.63	59.00	63.05
Candle-power	10.00	9.17	6.70	6.50	5.00
L ₂₀	10.96	10.58	10.89	10.47	10.26
Gas yield	52.00	55.00	61.21	56.43	66.48
Candle-power	9.17	8.33	6.20	8.50	5.50
L ₂₀	10.13	10.58	10.55	11.30	11.02

—J. T. C.

Weighting in Silk Yarn. The Quantitative Estimation of Herzfeld. Leipziger Färber u. Zeugdrucker Zeit. 45, 485.

ACCORDING TO E. Königs, Director of the Conditioning Establishment at Crefeld, the weighting is thus estimated:—(1) Estimate moisture by drying; (2) fatty matters by extraction with ether; (3) boil out silk glue with water; (4) dissolve out Prussian blue with alkali, re-precipitate with acid, and ignite precipitate with addition of HNO₃; 1 part of Fe₂O₃ = 1.5 parts of Prussian blue; (5) estimate SnO₂ present in ash of silk and calculate as catechu-tannate of tin, 1 part of SnO₂ = 3.33 parts of catechu-tannate; (6) estimate total Fe₂O₃, subtract that present as Prussian blue, and the amount naturally in the silk (0.4—0.7 per cent.), and calculate the remainder as tannate; 1 part of Fe₂O₃ = 7.2 parts of tannate of iron (or 5.1 per cent., if present as ferrous compound).

Moyret's directions for the determination of the weighting materials are as follows:—(1) Dry at 120°—130° C., if the loss exceed 15 per cent. the silk is weighted with hygroscopic materials; (2) boil in distilled water; in solution are glycerin, sugar, magnesium sulphate, &c.; (3) extract with ether to obtain fatty matters; (4) determine the nature of the weighting further by treating for 15 minutes with dilute hydrochloric acid (1:2) at 30°—40° C. Tannate of iron is indicated by the silk being decolorised to reddish-yellow, and the solution showing a dirty brown colour, which does not change to violet on dilution with cold water. If the solution be reddish and on dilution become violet, logwood is present. If the fibre be dark green, the solution yellow, and unchanged on dilution, the silk has been dyed with Prussian blue; and if the fibre be green and the solution pink, changing to violet on the addition of water, the dye is logwood black on a ground of Prussian blue.—R. B. B.

Starch, New Method of Estimating in Cereals. J. Effront. La Bière, 4, [10], 145—147.

THE grain being ground to an impalpable powder, 3 grms. are freed from fat when necessary, as in the case of maize, either by extraction in a Soxhlet apparatus, or merely by leaving in contact with ether in a tapped funnel for five minutes; the operation being performed three times, followed by washing with the same solvent and drying for half an hour at 100° C. The flour is then triturated in a glass mortar with 20 c.c. of concentrated hydrochloric acid (say, 49.92 grms. per 100 c.c.), added by degrees, and at the end of six minutes the whole is transferred to a 100 c.c. flask containing sufficient water to arrest the action of the acid, which will thus be restricted to the solution of the starch and its partial conversion into dextrin, very little, if any, glucose being formed. When carefully filled up to the mark the whole is well agitated and filtered through a folded filter, the residue being tested with iodine and examined under the microscope: if the trituration has been properly performed no granules of starch will be found, only the solution surrounding the solid particles being coloured blue. An accurately measured quantity (say, 75 c.c.) of the filtrate is taken and neutralised by caustic soda solution, an alkaline reaction being avoided; then concentrated to one-half on the water-bath, care being taken to preserve the liquid very faintly acid. On making the liquid up to the original bulk (75 c.c.), again it is filtered through a paper and a little asbestos until clear, and examined in the polarimeter (40 cm. tube). The residual liquid is titrated warm by the aid of 5 c.c. of cupro-tartrate solution diluted with 80 c.c. of water, the amount of glucose (g) per 100 c.c. being—

$$\frac{0.025 \times 100}{N} \text{ (the quantity, 9 c.c., used in the titration).}$$

R being the original reading (Soleil polarimeter, 20 cm. tube), the addition to be made for the glucose present, which is, in this case, calculated to dextrin, is represented by $R' [= g \times 4.8 (3.7-1)]$, and the percentage of starch in the 3 grms. of substance taken will be—

$$\frac{R + R'}{17.75} \times \frac{100}{3}$$

The precision of the method depends on the accuracy of the polarimeter reading, and it is therefore advisable to use a 40 cm. tube and a Laurent or Soleil apparatus on account of the larger size of the degrees. The results obtained are lower than those of the Maercker method, but correspond exactly to the amount of matter susceptible of fermentation, and, the formation of glucose being very minute, will afford accurate indication of the amount of ready-formed glucose, and therefore, of the procedure to be adopted in mashing.—C. S.

Starch in Cereals, Estimation of. L. Lindet. Bull. Soc. Chim. 1896, 15, 1163.

ABOUT 10 grms. of the grains are pounded up, placed in a conical flask, covered with water containing 1.5 c.c. of hydrochloric acid and 2 parts of pepsin (in scales) per cent., and the whole allowed to stand at 40° or 50° C. for 12 or 24 hours with occasional agitation. The object of

the pepsin is to dissolve the gluten that envelopes the starch granules; while the acid prevents the diastase from attacking any of the starch during the operation. The mass is then wrapped up in fine silk, and kneaded in a large quantity of water as long as anything passes through the fabric. The liquids are sterilised with formalin or mercuric chloride, the starch collected on a tared filter and finally dried, first at 50° and afterwards at 150° C. The filtration may be hastened by the addition of a weighed quantity of pumice.

The process is specially valuable in the examination of malt.—F. H. L.

Citric and Malic Acids, Detection and Separation of, by means of Quinine and Cinchonine. L. Lindet. Bull. Soc. Chim. 1896, 15, 1160.

Cold methylic alcohol (95° Gay-Lussac) only dissolves 0.3 per cent. of the acid citrate of quinine, so that addition of the alkaloid to a 2 or 2.5 per cent. solution of citric acid in that solvent produces a copious crystalline precipitate the weight of which may reach 93 per cent. of the theoretical yield. An excess of quinine redissolves the acid salt, and after a time the normal citrate falls, but the solubility of this compound is 3.3 per cent. Under similar conditions the acid and normal malate remain in solution, their solubility being 8.2 and 8.0 per cent. respectively. The presence of this acid somewhat hinders the precipitation of the acid citrate, and if the proportion of malic acid is 25, 50, 100, or 200 per cent. of the citric acid, the weight of the acid citrate is only 99, 97, 94, or 83 per cent. of what would be recovered in the absence of the disturbing substance. The acid and normal oxalates of quinine (solubility, 9.2 and 8.2 per cent.) also remain in solution, but this acid hinders the precipitation of the citrate even more than malic acid. The crystals of citrate may also be mistaken for the acid tartrate or succinate of quinine; the solubility of these compounds being 2.4 and 1.2 per cent. respectively.

Employed in the same manner, cinchonine behaves with malic acid as quinine does with citric, for although the solubility of the acid malate of cinchonine is higher (2.5 per cent.) than that of the acid quinine citrate, all the other cinchonine salts are so very much more soluble that the reaction is quite characteristic. The acid tartrate has a solubility of 20.6 per cent. in cold methyl alcohol, whilst the corresponding citrate, oxalate, and succinate only crystallise from a syrupy liquid. All these acids, however, notably increase the solubility of the malate.

In order to make use of these reactions, the vegetable juice is evaporated *in vacuo* and taken up in the strongest methylic alcohol. Any potassium bitartrate and free tartaric acid are removed by treatment with alcohol and ether, and the addition of a suitable amount of potash. The acids are then obtained in the free state by precipitation with basic lead acetate followed by sulphuretted hydrogen. Tannin must be absorbed by means of some animal matter such as violin strings. The free acids are finally dissolved in a small quantity of methyl alcohol, a portion of the liquid diluted till its strength is about 2.5 per cent., and increasing amounts of powdered quinine (not exceeding 160 to 170 per cent. of the citric acid expected to be present) are added until the mass crystallises. The requisite quantity of alkaloid being thus determined, another portion of the undiluted alcoholic solution is precipitated with quinine, filtered after standing 12 or 24 hours, the deposit well pressed, and the mother-liquors treated over again. Should no precipitate be obtained, proving that citric acid is absent, a fresh portion of the liquid is treated in a similar way with cinchonine (employing not more than 140 to 150 per cent. of the probable malic acid). In the event of both acids being present, the cinchonine may be added to the filtrates from the quinine precipitate.

The author has succeeded in extracting the citric acid from lemons, strawberries, raspberries, and tomatoes; and malic acid from cherries and grapes by this process.

—F. H. L.

Otto of Roses, Note on. Conroy. Read before the Liverpool Chemists' Association. Chem. and Druggist, 1896, 49, 771.

The author states that both the physical and chemical tests for detecting adulteration of otto of roses are useless for practical purposes.

He found that the freezing point of 65°–68° F. allows of 11 per cent. admixture of geranium oil.

The specific gravity test at 86° F., ranging from 0.850 to 0.856, allows of 15.8 per cent. admixture of geranium oil.

The optical rotation test of –2.3° to –2.7° allows of 5.5 per cent. admixture of geranium oil, or with an unlimited amount, if the rotation figures of the geranium oil be rectified by the addition of 5 per cent. of citrene.

The author thinks that the odour forms the best test, and gives the following method of detecting it:—Dissolve one drop of the otto in about 20 drops of rectified spirit. Pour this into 1 oz. of warm water (about 100° F.) and shake up well. If the odour of this be compared with that of the best standard sample obtainable, treated in a similar manner, there should be no difficulty in detecting an admixture of 5 per cent. of geranium oil.—A. S.

Otto of Roses, The Characteristics of. J. C. Umney. Chem. and Druggist, 1896, 49, 795.

To test the truth of the statement that the odour test is more reliable for determining the purity and commercial value of otto of rose than any chemical or physical characters, the author examined several specimens (Turkish), with the choicest fragrance, of this year's distillation.

Specific Gravity.—This is a fairly reliable indication of the proportion of stearoptene present, and examination shows that the specific gravities of the choicest ottos vary from 0.856 to 0.860 at 30° C. (this temperature is the most convenient for observation). The presence of geranium oil raises the specific gravity considerably, and samples testing 0.861 and upwards should be viewed with suspicion.

Melting and Crystallising Points.—These points are not easy to determine, the rapidity of cooling and warming having a considerable influence on the readings obtained. The finest ottos crystallise at 20.4° to 21° C., a higher temperature indicating excess of stearoptene and a consequent weakening of odour value.

Percentage of Stearoptene.—This is determined by careful fractionation under reduced pressure, the portion not distilling below a temperature corresponding to 240° C. at ordinary pressure being dissolved in chloroform, precipitated by addition of absolute alcohol, and purified by repeated washing. The stearoptene thus obtained was found to melt at 34° C., and had a specific gravity of 0.866 at 15° C., whilst at 40° C., in a liquid condition, its specific gravity was below 0.800, owing to the great expansion. It was found that the finest ottos, having specific gravities of 0.857 to 0.859 at 30° C., and crystallising points of 20.1 to 21° C., contained 16 to 18 per cent. of stearoptene.

Determination of Alcoholic Constituents.—In the varieties of otto of roses having the finest odour, an alcoholic percentage (determined by the acetylation process, and calculated on the formula $C_{10}H_{15}(O)$ equal to 71 to 72.5 per cent. is indicated. An abnormal stearoptene percentage reduces this figure materially (see No. 5), whilst admixture with Turkish geranium oil, which usually contains almost 85 per cent. of alcohols, raises the percentage considerably (see Nos. 7 and 8).

By the application of these physical and chemical tests to a sample of otto of rose, it is quite possible to determine its quality: admixture with Turkish geranium oil raises the specific gravity and the proportion of alcoholic bodies present, whilst it lowers the crystallising point and the percentage of stearoptene. The characters of the finest ottos of this season's production are as under, and may be accepted as standards of excellence:—Specific gravity at 30° C., 0.856 to 0.860; stearoptene percentage, 16 to 18; crystallising point 20.4° to 21° C.; alcoholic percentage (by acetylation process), 71 to 72.5.

The following table contains the results of this examination:—

—	Specific Gravity at 30° C.	Crystallising Point.	Approximate Percentage of Stearoptene.	Percentage of Alcohols calculated on $C_{20}H_{34}O$.
No.		° C.		
1	0.8566	20.9	18	70.1
2	0.8599	20.4	16	72.3
3	0.8610	20.0	11	73.1
4	0.8590	20.6	16	72.3
5	0.8560	21.7	19.5	69.2
6 (impure)	0.8630	19.4	12.5	75.6
7 (impure)	0.8680	18.7	10	77.6
8 (impure)	0.8680	18.9	10	76.6

—A. S.

Ethereal Oils, Valuation of. Schimmel and Co. Chem. Centr. 1896, [22], 977.

Bergamot Oil.—Density, 0.882—0.886. Optical rotation at 15°—20°, +8° to 20° in 100-mm. tube. Adulteration with oils of turpentine, lemon, orange, also with alcohol, and distilled bergamot oil, lowers the density, whilst fatty oils, cedar oil, or Gurjun balsam oil increase it. The pure oil dissolves in half its volume of 90 per cent. alcohol, but does not give a clear solution in 80 per cent. alcohol, the insoluble constituents being probably waxes. The residue on distillation is 5—6 per cent.; more than this would indicate the presence of fatty oils. The important constituent is linalyl acetate; this is determined by boiling with $\frac{1}{2}$ N alcoholic potash for half an hour, adding water, and titrating with $\frac{1}{2}$ N sulphuric acid, using phenolphthalein as indicator.

Lemon Oil.—Density, 0.858—0.861 at 15°. Optical rotation, +59° to +67° at 20°, usually only +64°. The difference in rotation for 1° C. between 10°—20° is -9°, between 20°—30° it is -8.2°; thus an oil with the rotation +63° at 10° C., has only 61° 30' at 20° C. Adulteration with oil of turpentine alone is recognised by the lessened rotation, but if at the same time oil of orange is present the following method must be used:—10 per cent. of the oil is slowly distilled from a Ladenburg's distilling flask with three bulbs, and its rotation determined. Since pinene boils at a lower temperature than limonene, this fraction will have a considerably lower rotation if oil of turpentine be present. Thus, a lemon oil with the rotation +61° 52' gave a 10 per cent. fraction with the rotation +58° 55' at 20° C., but the same lemon oil after the addition of 7.1 per cent. of orange oil (rotation +96° 23'), and as little as 2.9 per cent. of French turpentine oil (rotation -28° 24'), gave a fraction of rotation 54° 28', showing a difference from the original rotation of -7° 17' as compared with -2° 57' when the pure oil was used. The results of the process depend so much on the manner of distillation that it is necessary to perform a check experiment with an oil of known purity.

Orange Oil.—Density, 0.848—0.852 at 15° C. Rotation, +96° to +98° at 20° C. in 100-mm. tube. All adulterants, oil of turpentine, spirit, oil of lemons, considerably decrease the rotation. Oil of turpentine may be detected as above described, but it is advisable to repeatedly fractionate with a dephlegmator. Bitter orange oil at times has a lower rotation, +92°.

Oil of Lavender.—Density, 0.883—0.895 at 15° C. Rotation, -4° to -8° in 100-mm. tube. The pure oil dissolves in three volumes of 70 per cent. alcohol. The important constituent is linalyl acetate, together with a little geranyl acetate. The value of an oil is in direct proportion to the ester content (compare Duyk, this Journal, 1896, 919), which is determined as in the case of bergamot oil; it should be at least 30 per cent.; very good oils may contain more than 40 per cent.

Oil of Cloves.—Methyl alcohol and furfural have been found. The latter is possibly the cause of the darkening of certain oils.

American Oil of Peppermint.—Amyl alcohol and small quantities of sulphur compounds (dimethyl sulphide) have been detected.

Oil of Rue.—Density, 0.833—0.840. Rotation, +0° 13' to +2° 10' in 100-mm. tube. The pure oil gives a clear solution in 2—3 parts of 70 per cent. alcohol, and crystallises at 8°—10° because of the separation of its principal constituent, methyl nonylketone.

Oil of Rosemary.—French and Italian. Density exceeds 0.900. Slightly dextro-rotatory. The pure oil gives a clear solution in half its volume of 90 per cent. alcohol and in 10 parts of 80 per cent.—A. C. W.

Caffeine, Notes on the Estimation of. W. A. Puckner. J. Amer. Chem. Soc. 18, [11], 978—981.

GOMBERG has stated that those methods of estimation are inaccurate which involve shaking out the caffeine with chloroform from an aqueous solution. The author supports Allen's opinion that four extractions with chloroform, from a solution slightly acidulated with sulphuric acid, effect complete extraction. He quotes experiments in which 0.1285 to 0.4416 gm. of anhydrous caffeine was dissolved in 50 c.c. of 1 per cent. sulphuric acid, and shaken successively with 25, 10, 10, and 10 c.c. of chloroform, the chloroform solution evaporated at a gentle heat, and the residue dried over sulphuric acid to constant weight. From 99.55 to 99.92 per cent. of the caffeine was thus recovered.

Gomberg quoted an experiment in which a solution of caffeine in "(1:10)" sulphuric acid, on shaking out 16 times with chloroform, gave less than 50 per cent. of the caffeine used. The author repeated the experiment, and obtained from 65 to 90 per cent. in the first three extractions. Such strongly acid solutions should not be used, else the extraction of the caffeine is hindered.—H. B.

Sherry Wine. E. W. Lucas. Pharm. J. 1896, 57, 397.

See under XVII., page 914.

XXIV.—SCIENTIFIC & TECHNICAL NOTES.

Bromcyanogen, Preparation of, &c. R. Scholl. Ber. 1896, 29, 1822—1825.

A SOLUTION of 65 grms. of potassium cyanide of 96—98 per cent. strength, in 120 grms. of water, is cooled to 0° C. and added gradually (drop by drop), with frequent shaking and cooling with ice, to 150 grms. of bromine on the surface of which a little water has been placed. The reaction proceeds quantitatively. If, in spite of the ice cooling, the temperature of the mixture rise temporarily to 30° C., as it may, no injury results. Finally the liquid becomes a crystalline pasty mass. This is probably a double compound of bromcyanogen and potassium bromide. The cyanide should have been added until the bromine colour of the liquid just passes into yellow, but no farther. The whole mass is next transferred to a retort and distilled on the water-bath at a temperature of 65° to 70° C., whereby, from the 150 grms. of bromine used, about 90 grms. of damp bromcyanogen are obtained in snow-white needles (90 per cent. of the calculated quantity). It can be dried over calcium chloride.—E. B.

Nitrogen Iodide, Constitution of the so-called. F. D. Chattaway. Proc. Chem. Soc. 1896, [169], 172—174.

From the beginning of the present century, the black explosive compound formed when a solution of ammonia acts upon iodine, has almost continuously engaged the attention of the chemists. No definite conclusion as to its constitution has, however, been arrived at, although, from time to time, different formulae have been assigned to it, while, on account of its apparently variable composition, several distinct compounds have been supposed to exist.

The formulae NI_3 , NI , NH_2I , NH_4I , and NH_2NI_3 , have been adopted by various chemists, whilst others have suggested that a series of different but allied substances exist, derived either from NH_3 , or a hypothetical substance, $II_3N.NH_3$, by replacement of hydrogen.

On the whole, it seems that a single substance is formed by the action of ammonia on iodine, and that in this, one atom of nitrogen is associated with two atoms of iodine.

Whether the simplest formula that can be given to the substance is NH_4I_2 or NH_4I_2 can only be finally settled by a very careful investigation of all its reactions under the most varied conditions; but at present the formula NH_4I_2 seems best to accord with the reactions of the substance and to express the known facts regarding it.

New Books.

CHEMISTRY FOR ENGINEERS AND MANUFACTURERS. A Practical Text-book. By BERTRAM BLOUNT and A. G. BLOXAM. With Illustrations. Vol. II.—Chemistry of Manufacturing Processes. Chas. Griffin and Co., Ltd., Exeter Street, Strand, London. 1896. Price 16s.

VOL. I. received descriptive notice in this Journal, 1896, 225, the present book being Vol. II., and completing the work. The text fills 436 pages, and there is an alphabetical index covering 43 pages, immediately preceded by a bibliographic index of 3½ pages. The leading subjects treated of in this section of the work—Vol. II.—are the following:—I. Sulphuric Acid Manufacture; pages 1–17. II. Manufacture of Alkali and its By-Products; 19–53. III. Destructive Distillation; 55–104. IV. Artificial Manure Manufacture; 107–114. V. Petroleum; 117–124. VI. Lime and Cement; 126–141. VII. Clay Industries and Glass. VIII. Sugar and Starch. IX. Brewing and Distilling; 189–222. X. Oils, Resins, and Varnishes; 223–246. XI. Soap and Candles; 247–255. XII. Textiles and Bleaching; 257–265. XIII. Colouring Matters, Dyeing and Bleaching; 270–343. XIV. Paper and Pasteboard; 344–347. XV. Pigments and Paints; 349–366. XVI. Manufacture of Leather, Glue, and Size; 367–395. XVII. Explosives and Matches; 398–411. XVIII. Minor Chemical Manufactures, 413–434, among which are included the Chromates, Manganates, and Sulphates, Potash Salts, the Halogens, Cyanogen Compounds, and Bisulphide of Carbon.

TABELLARISCHE UEBERSICHT DER IN HANDEL BETRIEBLICHEN KÜNSTLICHEN ORGANISCHEN FARBSTOFFE. Von GUSTAV SCHULTZ und PAUL JULIUS. Dritte vollständig umgearbeitete und stark vermehrte Auflage. Herausgegeben von Dr. GUSTAV SCHULTZ. Hermann Heyfelder, Berlin. H. Grevel and Co., 33, King Street, London. 1897. Price M. 20.

NOTICE of the Second Edition of this work appeared in this Journal, 1891, 662. The present Third Edition is completely re-written, and contains many additions of value. There is a preface, a table of contents, list of abbreviations, and indexes of initials representing certain typical constitutional forms, technical terms for certain chemical compounds, and abbreviations for journals and works of reference. The tables extend from page 2 to page 201, and give descriptions of 504 different colouring matters, whilst the alphabetical index fills 14 pages. It is worthy of mention that whereas 401 dyestuffs were described in the last edition, 87 have since 1891 been abandoned, as no more in the trade, whilst 187 new ones have appeared, and are described in the present volume.

NOTES: QUALITATIVE ANALYSIS. Arranged for the Use of Students of the Reusscher Polytechnic Institute. W. P. MAXON, Professor of Chemistry. Third Edition. Chemical Publishing Co., Easton, Pa., U.S.A. 1896. Price 0·8 dol.

THIS little work contains preface and 56 pages of text. It contains, first, the reactions of ordinary bases and acids, &c., and after these, tabulated schemes for qualitative analysis. Then follows an appendix, with methods for the preparation of reagents, coloured flame- and borax bead-reactions, examinations on charcoal before the blow-pipe flame, &c.

THE CHEMICAL ANALYSIS OF IRON. A Complete Account of all the best known Methods for the Analysis of Iron, Steel, Pig-Iron, Iron Ore, Limestone, Slag, Sand, Coal, Coke, and Furnace and Producer Gases. By ANDREW ALEXANDER BLAIR, Chief Chemist, United States Board

appointed to test Iron, Steel, and other Metals, 1875, &c. Third Edition. J. B. Lippincott Company, Philadelphia, U.S.A.; and 10, Henrietta Street, Covent Garden, London. 1896. Price 18s.

LARGE 8vo volume, containing dedication, prefaces to Third, Second, and First Editions, table of contents, and subject-matter filling 313 pages. An appendix on the Determination of Nickel and Aluminium in Steel follows, and thereafter the alphabetical index. The work is illustrated by 103 engravings, representing forms of apparatus, &c., and between pages 303 and 313, a series of tables of constants, factors, and data for Reducing Volumes of Gases to the normal state.

After descriptive paragraphs on apparatus for the preparation of samples, and for general laboratory purposes, the work treats of the following themes:—Reagents; Methods for the Analysis of Pig-iron, Bar-iron, and Steel. Determinations of Graphitic Carbon, Combined Carbon, Titanium, Copper, Nickel and Cobalt, Chromium and Aluminium, Arsenic, Antimony, Tin, Tungsten, Vanadium, Nitrogen, Iron. Methods for the Analysis of Iron Ores; for the Analysis of Limestone; Clay; Slags; Fire-Sands; Coal and Coke. Methods for the Analysis of Gases.

DEUTSCHLAND'S SODA-INDUSTRIE IN VERGANGENHEIT UND GEGENWART. Ein kritischer Beitrag zur Geschichte der deutschen Zollpolitik. Von Dr. J. GOLDSTEIN. Mit einem Vorwort von WALTHER LOTZ. J. G. Cotta'schen Buchhandlung Nachfolger, Stuttgart, Germany. 1896. Price M. 2·40.

8vo volume containing 108 pages of subject-matter, preceded by bibliographic table, table of contents, and preface by W. Lotz, of Munich. The text is classified into three chapters:—I. Treaty of Commerce with France. The New Tariff. The Position of the German Soda Industry at the beginning of the Year 1860. The Salt Monopoly. Import and Export of Products of the Soda Industry. Treaty of Commerce with England. Removal of the Salt Monopoly. Position of the Industry at the beginning of 1870. Tariff Reform of 1873. II. Commercial Crisis and Protective Duty Agitation. Society for Guarding the Interests of German Chemical Industry and the Soda Duties. Reduction of the Prices of Alkali and the Reasons. Extension of the Ammonia-Soda Manufacture, &c. III. Present Position of the Alkali Industry in England and Germany. Complaints of those interested, and the Reality. Retrospect, &c. This work is one of a series published by L. Brentano and W. Lotz, and entitled, "Die Münchener Volkswirtschaftlichen Studien," the present being the thirteenth of a series.

EINFÜHRUNG IN DAS STUDIUM DER ALKALOIDE, mit besonderer Berücksichtigung der vegetabilischen Alkaloide und der Ptomaine. Von Dr. IGILIO GUARESCHI. Mit Genehmigung des Verfassers in Deutscher Bearbeitung. Herausgegeben von Dr. HERMANN KUNZ-KRAUSE. Erste Hälfte. 1896. Hermann Heyfelder, Schönebergerstrasse 26, Berlin, S.W. H. Grevel and Co., 33, King Street, Covent Garden, London. Price M. 18.

THIS is the translation into German from the Italian of Guareschi's "Introduzione allo Studio degli Alcaloidi." The translation has been undertaken by Dr. Hermann Kunz-Krause. The translated work is published in two parts, and the present is Part I. It is a quarto volume, unbound, and containing preface to the German edition, and 304 pages of subject-matter. The completed work, it is claimed, will furnish a full and systematic review of the whole subject of the nitrogen compounds in general which possess a basic character, *i.e.*, Alkaloids in the full sense, and also the Ptomaines and Leucomaines. The first section of the work is subdivided as follows:—I. Bases with open chain. II. Bases with closed chain. III. Arrangement of those natural organic bases the constitution of which has been determined with certainty. IV. Those Alkaloids, arranged according to the natural botanic orders, the constitution of which yet remains either doubtful or unknown. V. The Ptomaines and Leucomaines, treated according to their position in the classification adopted, as also in their relations to Chemical Jurisprudence and Pathology.

Trade Report.

OFFICIAL NOTICE.

UNHEALTHY OCCUPATIONS.

Chem. Trade J., Dec. 12, 1896, 374.

The Home Secretary certifies that the process of *vulcanising india-rubber* by means of bisulphide of carbon, and the processes incidental thereto, are dangerous or injurious to health. The Chief Inspector of Factories may, consequently, serve on the occupier of the factory or workshops a notice in writing either proposing such special rules or requiring the adoption of such special measures as appear to be reasonably practicable and meet the necessities of the case.

TARIFF CHANGES AND CUSTOMS REGULATIONS.

(From the Board of Trade Journal.)

GERMANY.

Freights for Manures.

A notice has appeared in the *Reichsanzeiger* to the effect that the Prussian Government have agreed, in view of the depressed condition of agriculture, to extend the 20 per cent. reduction in freights for manures which was granted on the State Railways from March 1, 1895, to May 1, 1897, for a further period of five years.

INDIA.

Adulterated Goods and the Merchandise Marks Act.

1. The Government of Madras referred, for orders, a question as to the trade descriptions which should be affixed, under the Indian Merchandise Marks Act, IV. of 1889, on packages containing adulterated goods, such as oils, turpentine, paints; and the attention of the Government of India was drawn to the diversity of practice at Madras and Calcutta in the matter of amending the descriptions on such packages.

2. At Madras, packages containing adulterated linseed oil and red lead are not permitted to pass into consumption unless the word "adulterated" is plainly stencilled on the drums containing the articles, whereas at Calcutta such goods are passed if they are marked "reduced," "mixed," or "mineral," on every label describing them.

3. On inquiry from the Government of Bombay it has been ascertained that at the Bombay Custom-house no objection is taken to the importation of packages of adulterated linseed oil and red lead if they are described as "boiled" oil and "reduced" red lead. It is stated, however, that the term "reduced" used in connection with red lead is only applied to a composition which contains at least 50 per cent. of red lead; if the quantity of red lead is less than 50 per cent., the actual percentage of red lead must be indicated on the drums.

4. The practices at Bombay and at Calcutta are substantially the same, and they appear sufficiently to carry into effect the provisions of the Merchandise Marks Act. As there should be uniformity in such matters, it is expedient that the practice should be adopted at all other ports in India.

ITALY.

The Importation of Patent Medicines into Italy.

The official *Bollettino di Notizie Commerciali*, in a recent issue, publishes, *in extenso*, a list of patent medicines, the importation of which into Italy is permitted; and, likewise, a list of medicines in which the quantity of spirit contained therein or consumed in their manufacture has been determined.

These lists may be seen at the Commercial Department of the Board of Trade, 7, Whitehall Gardens, S.W., between the hours of 11 and 5.

UNITED STATES.

Customs Decisions.

Naphthalene is exempt from duty as a coal-tar preparation other than medicinal, under paragraph 443.

Refined carbonate of potash is dutiable at 25 per cent. *ad valorem*, under paragraph 60, as a chemical salt.

Colours of any kind, in tubes, are assessed at 25 per cent., under paragraph 18.

WESTERN AUSTRALIA.

Customs Duties Repeal Act, 1896.

The Board of Trade have received from the Registrar-General of Western Australia copy of an Act assented to on Sept. 30 last, by which the Customs duties on the following articles are repealed from Oct. 1 last:—

Asbestos; asphaltum; boiler fluid; candle makers' materials, including Japan wax; crucibles; cyanide; dyers' materials; metals not otherwise enumerated; oil and turpentine, other than in bottles; paper (unprinted) in the flat, in original wrappers; quicksilver; resin, pitch, and tar; retorts; smelting material not otherwise enumerated; soap-makers' materials, (including caustic soda, resin, cocoa-nut oil, palm oil, and olein); soda ash and nitrate of potash; tanning materials—sumach, myrobolams, valonia.

NEW CUSTOMS TARIFF OF VICTORIA.

The following is a statement of the duties now leviable on articles imported into the Colony of Victoria:—

Note 1. All articles not specially mentioned as dutiable, or which cannot be classified under one of the dutiable headings in this list, will be admitted free.

2. The Customs and Excise Duties Act, 1895, provides that the articles mentioned as free in this list, and no others, shall be exempted from the payment of the duties which, but for their specific exemption, would otherwise be payable thereon.

3. Where a number appears before any item, it is to be understood that the wording is that of the Customs and Excise Duties Act, 1895.

Import Duties.

No.	Articles.	Rate of Duty.
	Acids, viz.:—	
1	Acetic, containing not more than 30 per cent. acidity.	3 <i>d.</i> per pint or lb.
	Acetic, for every extra 10 per cent. or part of 10 per cent. above 30 per cent.	1 <i>d.</i> per pint or lb.
2	Muriatic, nitric	5 <i>s.</i> per cwt.
3	Sulphuric	1 <i>s.</i> per cwt.
	Ammonia (liquid)	Free.
	" carbonate	2 <i>d.</i> per pint or lb.
37	Bitumen, bone pitch, Egyptian and Assyrian asphaltum, sweated or prepared pitch, Swedish asphaltum, Stockholm pitch.	Free.
38	Blacking, including burnishing ink, dressing, harness polishing, and paste.	2 <i>s.</i> <i>ad val.</i>
39	Black lead and polishes made of plumbago, in packages of less than 2 lb. weight.	20 " <i>ad val.</i>
	Blue	2 <i>d.</i> per lb.
	Candles	1 <i>d.</i> per lb.
		(Jan. 1st, 1897.)
	Carbons (electric)	Free.
113	Cement, including plaster of Paris and other products having sulphate of lime as a basis.	1 <i>s.</i> per cwt.
	Cements, liquid	20 " <i>ad val.</i>
114	Charcoal and coal (ground)	20 " <i>ad val.</i>
115	" (animal, ground)	Free.
	Chemicals and drugs, packed ready for retail sale or consumption, including medical compounds containing spirits not exceeding the strength of proof by Sykes' hydrometer.	25 " <i>ad val.</i>
117	China ware and porcelain	15 " <i>ad val.</i>
118	" being photographic, scientific, and telegraphic materials.	Free.
	Chlorodyne	Free.
	Cocculus indicus	1 <i>s.</i> per lb.
	Cocoa	3 <i>d.</i> per lb.
121	" raw	Free.
	Cocoa-nut oil, in bulk	Free.
124	Colours, artists'	Free.
	Crucibles (metal)	Free.
	Driers, patent	2 <i>d.</i> per ton.

NEW CUSTOMS TARIFF OF VICTORIA—*cont.*

No.	Articles.	Rate of Duty.
	Essences and essential oils, not containing alcohol.	Free.
	Essences, culinary. <i>See</i> "Spirits."	
	Essential oils and essences, not containing alcohol.	Free.
149	Explosives, being fine meal powder, not sporting, in bulk and in packages of not less than 25 lb. each.	Free.
150	Common blasting powder.	Free.
151	Powder, sporting.	3d. per lb.
152	Other explosives.	1d. per lb.
	Fuse.	1d. per coil of 21 ft.
	Fireclay goods, not otherwise enumerated.	2d. <i>ad val.</i>
	Fireclay, or brown or cane, medical and sanitary ware (earthenware).	8d. per cubic foot.
158	Fireworks.	20° <i>ad val.</i>
	Glucose.	6s. 6d. per cwt.
203	Glue, liquid, and liquid gum and cements.	20° <i>ad val.</i>
204	Glue.	2d. per lb.
136	Glycerine, pure.	1d. per lb.
137	" crude.	1d. per lb.
241	Ink, printing (coloured).	6d. per lb.
242	Inks, writing, liquid or powder.	10° <i>ad val.</i>
	Ink, burnishing.	25° <i>ad val.</i>
255	Lead, sheet and piping.	28. 6d. per cwt.
256	Leaf, gold and silver.	20° <i>ad val.</i>
	Leather:—	
257	Being crust or rough-tanned calf, goat, horsekin, sheep, or kangaroo, when not exceeding 7 lb. each skin; English bend, sometimes called butt.	Free.
258	Kid, calf kid, mock kid, and patent calf.	Free.
259	Hoeskins.	Free.
	Beltine (machine).	35° <i>ad val.</i>
260	Furniture, bootmaking and book-binding morocco (except black), Persian sheep, roan and skivers.	35° <i>ad val.</i>
261	Black morocco and goat levant.	20° <i>ad val.</i>
262	Not otherwise enumerated.	6d. per lb.
	Maize-flour or corn-flour.	2d. per pint or lb.
	Maizena.	2d. per pint or lb.
280	Matches, wood safety.	Free.
		12s. per gallon of the strength of proof by Sykes' hydrometer, and so in proportion for any greater or less strength than the strength of proof, when not dutiable at a higher rate under the heading of medicines liable to 25° <i>ad val.</i>
	Medical preparations containing alcohol.	25° <i>ad val.</i>
		10° <i>ad val.</i>
	Mineral waters.	6s. per cwt.
	Molasses, refined.	5s. per cwt.
	" in bond.	2s. per cwt.
	" unrefined.	2s. per cwt.
	Morphia.	Free.
	Muntz metal, in circles not less than 24 inches in diameter.	Free.
	Nitrate of silver.	Free.
	Nux vomica.	Free.
412	Oil and paste, furniture.	20° <i>ad val.</i>
	Oil and other floorcloth (except cord and jute matting otherwise dutiable).	15° <i>ad val.</i>
413	Oil in bulk, being cocoa-nut, 1-lb. of all sorts, mineral refined, of which the point of ignition is below 80° F.; kerosene, palm, lubricating, of which the chief component part is mineral, and resin.	Free.
	Oil silk.	Free.
	Oleomargarine and butterine.	1s. per lb.
424	Opium, including all goods, wares, and merchandise (except medical preparations) mixed or saturated with opium, or with any preparation or solution thereof, or steeped therein respectively.	17. per lb.
		17. per lb. of opium contained therein, when not dutiable at a higher rate under the head of medicines liable to 25° <i>ad val.</i>
125	Medical preparations containing . . .	Free.
	Optical, surgical, and scientific instruments (glassware).	Free.

NEW CUSTOMS TARIFF OF VICTORIA—*cont.*

No.	Articles.	Rate of Duty.
	Optical and scientific instruments (metal).	Free.
	Paints and colours:—	
428	Ground in oil, including patent dryers and putty.	2d. per ton.
429	Mixed ready for use, from or of any substance.	4d. per ton.
439	Paraffin wax.	1d. per lb.
	Parclement, cut.	20° <i>ad val.</i>
	" vegetable (used for packing or wrapping butter).	Free.
	Paste and polishing, harness.	25° <i>ad val.</i>
	Perfumery.	20° <i>ad val.</i>
453	Pitch.	25° <i>ad val.</i>
	Plaster of Paris.	1s. per cwt.
	Powder. <i>See</i> "Explosives."	
459	Powders, baking, scidlitz, washing.	20° <i>ad val.</i>
	Shoepwash (tobacco), including tobacco soaked on the landing thereof from the importing ship, or on delivery from the warehouse, in turpentine, oil, or other fluid in the presence of some officer of Customs, sons to render it unfit and useless for human consumption.	Free.
486	Soap, perfumed and toilet.	4d. per lb.
487	" other.	2d. per lb.
488	Soda crystals.	2d. per ton.
491	Spirits, cordials, liquors, or strong waters, sweetened, or mixed with any article so that the degree of strength cannot be ascertained by Sykes' hydrometer (including all alcohol diluted or undiluted with water or other non-trim, and containing in solution any essence, essential oil, ether, or other flavouring or other substance, whether of natural or artificial origin).	12s. per gallon.
	Spirits:—	
492	Methylated.	1s. per liquid gallon.
493	Perfumed.	1d. 1s. per gallon.
		12s. per gallon of the strength of proof by Sykes' hydrometer, and so in proportion for any greater or less strength than the strength of proof.
494	Culinary essences.	2d. per lb.
497	Starch.	1d. per lb., and after 1/198 1d. per lb.
516	Stearine.	Free.
	Strychnine.	12s. per cwt.
	Sugar, not being produce of cane.	6s. per cwt.
	" produce of sugar cane.	2s. per gallon.
577	Varnish, including lithographic.	6d. per gallon.
579	Vinegar, not being acetic acid or crude, aromatic or raspberry.	2d. per ton.
	White lead, dry.	Free.
	Zinc, sheet.	Free.

UNTAXED ALCOHOL FOR THE MANUFACTURES AND ARTS IN THE UNITED STATES.

Textile Colorist, 1896, 337; and *Oil Paint and Drug Reporter*, Nov. 30, 1896, 17.

The Joint Select Committee, created at the last session of Congress to investigate and report upon the question of the use of alcohol free of tax in the manufactures and arts, have prepared a series of interrogatories, which will be distributed throughout the country to such parties as are thought to be interested in the question.

The report of Mr. Henry Dalley, jun., who was commissioned to investigate the workings of foreign laws governing the use of untaxed alcohol in the manufactures and arts, contains very full and extremely valuable data covering Great Britain, Germany, France, Belgium, and Switzerland, and is given below.

It is the earnest desire of the Committee to secure all possible information bearing upon the subject, and it is hoped that parties interested will submit their views to the Committee promptly. Sets of the circular letter and blank for replies will be supplied to any applicant by addressing the Chairman, Room 21, Senate Annex, Washington, D.C.

The following is the letter of inquiry:—

Joint Select Committee of Congress on Alcohol in the Manufactures and Arts.

DEAR SIR,

At the last session of Congress a Joint Select Committee of the two Houses was created to obtain information with regard to the use of alcohol in the manufactures and arts free of tax, and to investigate all matters relating thereto. In furtherance of this object will you communicate to the Committee any information at your command upon the following points:—

1. How much alcohol is used in the United States in the business in which you are engaged, according to your best information?

2. How much do you use in your individual business?

3. Would there be an increased use of it in the trade with which you are connected if it were free of tax?

4. If so, to what extent?

5. Do you use wood alcohol or grain alcohol, or both, and if both, in what relative proportion?

6. Would methylated or unmethylated spirits be substituted for wood alcohol and other substances if they could be used free of tax in your manufacture?

7. What is the present difference of cost in this country between wood alcohol and grain alcohol, and has this difference fluctuated to any great extent?

8. Is the alcohol used in your business consumed in the process of manufacture, or does it form a part of the product offered for sale, or is it recovered?

9. What proportion of the total cost of the product manufactured by you is tax-paid alcohol?

10. If the alcohol remains in the product, could it be profitably recovered so as to be resold as alcohol either in the case of methylated spirits or of pure alcohol?

11. Would the use of alcohol free of tax in the business in which you are engaged lead to frauds upon the Treasury and a consequent loss of revenue? Please state fully.

12. Would the use of free alcohol in such business result in stimulating or increasing the exportation of your product?

13. Will you put yourself in communication with other parties engaged in your branch of business so that representatives of your industry may be prepared to give the fullest possible information upon the points above indicated, in addition to the reply which you make to this letter?

14. Is there an association representing your industry? If so, please give me the names of the officers and prominent members thereof, with their post office addresses.

Following is the text of the Commissioner's report upon the practical operation of the free alcohol laws of Great Britain, Germany, Belgium, and Switzerland:—

Great Britain—Distilling of Spirits.

The distilling of spirits in Great Britain is authorised by a license issued by the Commissioners of Inland Revenue. The distilled spirits must be stored in a "spirit store" at the distillery, in charge of a revenue officer, into which store all spirits distilled in the distillery must be conveyed. From this "spirit store" the spirits may be removed without payment of excise tax to an excise warehouse duly authorised by the Commissioners of Inland Revenue, said warehouse to be under the charge of an officer of the Inland Revenue, or the spirit may be warehoused without payment of tax in a distiller's warehouse.

Excise Tax and Drawback.

The present excise tax is 10s. 6d. per gallon, which must be paid upon withdrawal from warehouse for consumption, unless withdrawn for methylation. A reduction of tax for deficiency in quantity, indicated by regauging, and a specific allowance of 2d. per gallon upon withdrawal, are authorised by law.

Upon exportation of domestic spirits upon which the excise tax has been paid the allowance of drawback is 10s. 6d. per gallon, to which is added 4d. per gallon in the case of compounded spirits.

Methylation.

The English laws governing the use of alcohol free of tax relate exclusively to the use of methylated spirits. This system of tax-free methylated spirits originated in 1855.

The methylation of spirits must be done by either a distiller or a rectifier, authorised by the Commissioners of Inland Revenue, or by a methylator duly licensed by said Commissioners.

Methylation must take place in a warehouse provided by the Commissioners of Inland Revenue, in a building or room provided by the methylator and approved by said Commissioners. The spirits to be methylated must be at least 50 per cent. above proof, or, if rum be used, at least 20 per cent. above proof, and must be methylated in quantities of not less than 450 gallons, or, in the case of foreign spirits, the full contents of the cask in which the spirits were imported must be methylated. The methylating substance shall be approved by the Commissioners, and may be provided by the Government or the methylator, as the former shall determine, and shall equal at least one-ninth of the bulk of the spirits. The methylation must take place in the presence and under the direction of two Government officers, and when such methylation shall have been certified to by said Revenue officers, the spirits can be disposed of by the authorised methylator, subject to the limitations heretofore named.

Exportation of Medicinal and other Spirits.

Respecting the bearings of the English excise and export laws upon their different industries, the merchants were agreed in approving the Government's methods in vogue. The prime object of these English (as well as Continental) laws appears to be to foster to the fullest extent the exportation of home products. The result of this, as the history of the commercial world proves, is that England maintains its position as the leading nation in promoting this foreign commerce, and that its manufactures are found in all parts of the world, carried in English bottoms.

Not the least important element in the execution of these laws is the fact that the exportation is not only freely carried on by the merchants, but every assistance is furnished by the Government to accelerate and stimulate such exports. For instance, no delay is experienced between the notice of intention to export and the examination of the goods by the Government officials, and the examination is made at the place of manufacture; no unnecessary inquisitorial examination is made, the character of the merchants counting for something in the eyes of the law; no delay occurs in the filing of the certificate of shipment; and finally the drawback is payable on demand, although the custom of most merchants is to permit the drawbacks to accumulate for a month, when, by making a simple demand upon the proper fiscal officer, the amount standing to the merchant's credit, as shown by the certificates of shipment already filed, is promptly paid.

Frauds on the Revenue.

Special attention is called to an article in the Appendix relative to the frauds which have been discovered during the existence of the English laws governing the methylation of spirits, covering a period from 1855 to the present time.

The notable feature of this statement is that fraud is minimised, and that the policy of the Government is to extend rather than to limit the use of methylated spirits.

Germany.

The internal revenue tax in the United States on a proof gallon of alcohol is 1.10 dols. Absolute alcohol is gauged by a standard of 200°, and a proof gallon under U.S. law is "that alcoholic liquor which contains half its volume of alcohol."

The German internal revenue tax is about 72 cents per gallon on absolute alcohol.

The difference in the amount of internal revenue tax paid in the respective countries results in an advantage to the German over the American user of alcohol as follows:—

The American manufacturer starts out burdened with a tax of 1.10 dols. per gallon and a minimum cost of production

of 16 cents per gallon for the spirits, while the German manufacturer pays a tax of only 36 cents per gallon, and his cost for production of the spirits is but 12½ cents per gallon. The German manufacturer gains a still further advantage by the remission of the tax on alcohol, thus making competition in the foreign markets on the part of the American an impossibility and the holding of this domestic market very difficult under existing customs duties.

Again, the lowest customs duty in Germany on a gallon of absolute alcohol is about 1.35 dols., while the highest duty is equivalent to 3.67 dols. The duty on products containing alcohol (that is, beverages) is equivalent to 3.67 dols. per gall., the maximum duty. This duty is levied by weight upon the entire compound, and subjects the whole article to the highest alcoholic duty, regardless of the other component parts, thus in many cases subjecting the article to treble and even quadruple the duty which would be imposed did it consist entirely of alcohol, and this duty must be paid on the container also, which, being weighty, as in case of glass bottles, adds still further to the duty and makes it practically prohibitory. The effect of this policy is illustrated by the fact that during the year 1895 there were imported into the German Empire only 37,195 hectolitres, equivalent to 982,691 wine galls. of alcohol, mostly rum and brandy, and not alcohol for industrial purposes.

The importation of alcohol into Germany is rendered still more impracticable by the refusal to allow drawback upon it when exported, either as spirits or as alcoholic products.

Following the above illustration in respect to the German customs duty and internal revenue taxes, it is pertinent to the question to show that the German Government persistently pursues the policy of fostering home industries, even going so far as to do so at the expense of the general public, as illustrated in the bonus over and above the internal revenue tax which is paid to the exporter of domestic alcohol, and which is a drain upon the general revenues. Their internal revenue tax on alcohol amounts to the equivalent of 36 cents per gallon, United States measure, and this is refunded to the exporter of such alcohol or of products in which domestic alcohol is a component part, and in addition thereto a bonus equivalent to 75 cents per hectolitre, which is upon the cost of the alcohol (say 10 cents per gallon), about a 50 per cent. margin. This consists of bounty paid to the exporter of domestic alcohol or alcoholic products supplemented and made still further effective by the failure to allow a drawback on imported spirits exported.

Methylated Spirits.

The method of methylation in England is so complete that I deem it proper to suggest that if laws permitting the use of methylated spirits free of tax in the United States are enacted the Government could do no better than to pattern regulations after the English system, limiting such laws, however, to methylation at the distillery. I will not, therefore, go into the actual procedure of methylation as followed by the German Government, but will refer to the system in general, the policy of the Government relating to it, and the results which are obtained from its practice.

In a general way it may be said that the materials used for methylation and prescribed by the Government are wood alcohol, and in more recent years, that substance mixed with the pyridine bases (which are certain products of the residuum of coal tar, and are now largely known in commerce). This methylation is done by mixing four parts of wood alcohol with one part of the pyridine bases, and this is added to the pure spirits in the proportion of 2½ galls. of the methylating material to 100 galls. of pure spirits. Other methylating agents are used for specific purposes, full particulars of which will be found in the detailed report.

It may be well that I should state here that both in England and Germany the authorities admitted that methylated spirits could be partially purified, but in both countries the statement was made by the officials of the Government in the most unqualified manner that the frauds perpetrated in this way were so small the Government pays no special attention to them.

The methylation is performed under the supervision of the Government officials, and usually at the distilleries. Unlike the English system, there are no licensed methylators, and after methylation Government supervision ceases.

The German Government has in every way sought to make the policy of untaxed domestic spirits so complete as to be adaptable to every branch of industry requiring the use of spirits. Hence in the methylation of spirits many different agents have been devised to cover new fields of industry as they developed.

It should be noted that while these various methylating agents are specially permitted, their use is allowed only when the general methylating agent of wood alcohol and the pyridine bases is impracticable.

Untaxed Unmethylated Alcohol.

The system under which unmethylated alcohol is used in the arts and manufactures free of tax is as follows:—

The user (that is, the manufacturer) submits to the Government an approximate estimate of the quantity which he is likely to use within a year. As he has occasion he buys the alcohol to the best advantage, in quantities to suit, and notifies the Government of his purchases. The alcohol is then shipped to him from the distillery under the Government seal and surveillance, and the amount of spirits is charged against his estimated requirements.

He must then account for the use of this alcohol from time to time to the satisfaction of the Government officials, and at the end of the year, if any remains on hand, the quantity so remaining is charged against his requirements for the ensuing year. If during the year he requires more than his estimated quantity, and if his reputation is such as to command confidence, he is permitted to make further purchases according to his needs.

Manufacturers having occasion to use untaxed unmethylated alcohol for medicinal, scientific, and industrial purposes, are required to keep accurate books of account, and through these records to show how all the alcohol is disposed of. These books come from time to time under the examination of Government officials, to ascertain that the alcohol has been legitimately used, and that the quantities received, consumed, and remaining on hand properly tally. Such manufacturers are required to take account of stock semi-annually, and a Government inspection of their establishment takes place monthly.

Although this system of untaxed alcohol is working to the satisfaction of the German Government, without apparent fraud or friction, it would seem as if even more beneficial results would undoubtedly come from a system which would provide, first, for the payment of the internal revenue tax on all alcohol, and, second, for the refunding of this tax by the Government upon proof submitted by the manufacturer that the alcohol has been used according to the provisions of law.

From such a system would come, it seems to me, two very important results: first, the avoidance of minute and onerous espionage; second, the Government would, for the period prior to the refunding of the tax (say six months, or perhaps even a year), have the use of a considerable sum of money, which would remain in the treasury; third, the expenses of supervision would be largely reduced.

Belgium.

In Belgium there has been a High Commission investigating the laws of foreign countries relating to the use of alcohol free of tax in the arts and manufactures. This Commission has heretofore made a comprehensive report, containing much valuable data as the result of such investigation.

It seems to be well understood in Belgium that free alcohol under the most restricted conditions that are compatible with absence of fraud is demanded by the people, and that any legislature which ignores their expressed wishes in this direction would soon be retired. Therefore, measures in this direction are constantly under consideration, and sooner or later Belgium will be in line with the nations of Europe on this subject.

Switzerland.

The Government controls all the alcohol that is manufactured, imported, or sold in Switzerland. Distillers are permitted to manufacture to an extent which is limited by the authorities. Under these limitations they manufacture alcohol, and when their part of the process is completed, the alcohol, in a semi-crude state (that is, with more or less impurities), passes from the stills through pipes into the control of the Government officials. Account of the amount thus made is taken, and the distiller is paid so much per hectolitre for his product, the price being determined by the Government according to the conditions which may prevail in respect to the agricultural interests.

As to the system of methylation prevailing in Switzerland, suffice it to say that ordinary methylation has hitherto been done with methyl alcohol and pyridine bases, as in the case of other countries; but the Swiss Government is continually investigating other processes of methylation and adopting the superior methods.

Methylation for pharmaceutical and chemical products and for perfumery is done by the use of materials which are a part of the finished product.

DUTY ON CYANIDE OF POTASSIUM.

Eng. and Mining J., Dec. 5, 1896, 538.

In this case duty was assessed on cyanide of potassium at 25 per cent. *ad valorem* as a chemical salt under paragraph 60 of the customs law. Appellants claimed that it should be entered free under paragraph 443 as a coal-tar product. The appeal was overruled and the assessment under paragraph 60 was sustained. Schoellkopf, Hartford, and MacLagan, appellants, vs. Collector of the Port of New York; United States Board of General Appraisers.

EXTRACTS FROM DIPLOMATIC AND CONSULAR REPORTS.

CHEMICAL TRADE OF TURKEY IN ASIA.

Imp. Inst. J., Dec. 1896, 447.

The German Consul in Bagdad reports that, up to the present, drugs, chemicals, and pharmaceutical articles generally, are chiefly imported from Paris and Marseilles. Last year, however, Berlin manufacturers had begun to compete, and although thus far their share in the business is a small one, their goods have been favourably received. The aniline and general colour trade is entirely in the hands of German and Swiss firms. It is reported that some of the large German colour factories intend to establish in Bagdad a transit depot for supplying the western provinces of Persia with their goods. Within the last few months German and Austrian manufacturers from Karlsruhe, Zeitz, and Vienna have commenced to pay attention to this market.

THE DEVELOPMENT OF NEWFOUNDLAND.

Imp. Inst. J., Dec. 1896, 433.

An official report on the mineral resources of the colony, published in August last, gives an interesting account of the iron ore formation of Bell Island, in Conception Bay. Although not a high-grade ore, its abundance so near the surface, with unusual facilities of raising and shipping it, may render this a most valuable property. The present lessees have established plant capable of dealing with an output of 500 tons per diem when in full working order. At Tilt Cove, a mass of pyrites, said to be 200 ft. in thickness, and to contain 2 or 3 per cent. of copper, has been worked for some time. Pyrites occur in very many localities, and in almost all the great bays, in more or less quantity. With regard to the more generally useful ores of iron, the island possesses an abundance of the following:—Magnetite, chromite, clay iron ore, and hematite of several varieties, such as specular iron, red hematite, red ochre, jaspery iron ore. The deposits of magnetite are sometimes enormous; one band at Union Mine, Tilt Cove, ranges from 4 to 30 ft. in thickness, and is of very superior quality. The most extensive deposits, however, are found on the west coast of the island, near Bay St. George. An analysis

of this ore gives 65.05 per cent. metallic iron, but it contains a varying percentage of titanate acid. It is, however, absolutely free from sulphur and phosphorus. A large deposit of magnetic iron is indicated at a point in the interior, near the head of Bay d'Est river, amongst a set of serpentine and chloritic rocks. Chromic iron, or chromite, occurs very frequently, especially associated with the magnesian group of rocks, usually termed here serpentines; and hematite and its varieties are also of common occurrence in various parts of the island. With regard to coal, the report shows that at present there are two distinct coal areas that have been partially explored, one on St. George's Bay, and the other in the Grand Lake District. In the latter the coal measures are on both sides of the line of railway already built, and in close proximity to it, but the coal obtained will have to be conveyed over 45 miles of the line to reach the nearest point on the Humber river at which it could be shipped. In the St. George's Bay area, which the railway has now reached, there will be, under any circumstances, not less than 35 miles of railway carriage for the coal before it can be shipped at Port au Basque. For any continuous shipment of coal all the year round this port will have to be used, as it is free from ice in the winter. It is believed, after local tests, that the Newfoundland coal is a stronger and better coal than that of Sydney, with which it will have to compete in the market; but as the latter is run straight from the mine to the ship, the former will be heavily handicapped by the cost of railway carriage, unless mining labour can be obtained more cheaply in Newfoundland than in Sydney. It, therefore, remains a question whether Newfoundland coal—plentiful as it may be—can compete with the Sydney coal, even for the supply of the wants of the colony.

GENERAL TRADE NOTES.

THE WORKING OF THE INDIAN MERCHANDISE MARKS ACT.

Times of India, through Bd. of Trade J., Dec. 1896, 690.

THE reimposition of the import duties has had the effect of increasing, to the extent of something like 70 per cent., the number of detected infringements of the Merchandise Marks Act.

The total number of detentions during the year was 1,622, as compared with 955 in the previous year, and 1,287 in 1893-94. In Bombay the number of detentions was 918, as against 352 in the previous year; while in Calcutta the number was less than 400, which is, roughly speaking, the average of the five years during which the Act has been in operation. In Madras, including outports, the detentions number 101, as against 54 in the previous year, and 16 in 1891-92. Kurrahee's total was 136, as compared with 223 in the previous year, and 365 in 1892-93.

In Bombay there were only three cases of false trade marks, one being in respect of paper, and the other two in respect of alizarine dye, in spurious brands of which a very large trade used to be done a few years ago.

Some of the Bombay investigations revealed frauds of the most impudent kind. A large consignment of bottles was landed, for instance, all of which were marked "Quinine C." It was suspected that this so-called quinine was not genuine, and a sample was forwarded to the chemical analyser to Government. That gentleman reported that not only was the "quinine" not genuine, but that it contained no quinine at all; being, in fact, a cheap alkaloid of the cinchona bark. The ingenious contention of the manufacturers was that so long as they did not actually call the article "Quinine," but only "Quinine C.," no offence was committed. The plea, of course, was not entertained; but the Customs authorities allowed the fraud to pass on the payment of a penalty after an alteration had been made in the label, and no doubt it has long since passed into the bazaar as genuine quinine.

Then, again, there were several consignments of imitation gold and silver thread, made up and labelled in imitation of real gold and silver thread; and a large number of cases, in which an article labelled "Best 100 B touch Mexican Vermilion" was found to contain absolutely no vermilion whatever. In both these instances the goods were

passed on the payment of a fine, instead of being confiscated and destroyed.

Japan was, as usual, a great offender against the Act. The daring of her exporters seems to know no limit. Their ingenuity during the year under review was mainly confined to the export of pencils, clocks, soaps, umbrellas, and matches, all of which were fraudulently marked. In another instance, a case of false trade description was revealed by the exporters themselves, who wrote to the Customs authorities to say that although they called their consignment by the name of the Belmont Spermi candles, they did not contain a particle of spermaceti in their composition, and they asked therefore that the articles should be assessed at the lower rate for common candles. These too ingenious exporters now send their goods marked "Stearize" instead of "Spermi," which is, no doubt, the more excellent way, though it probably does not pay so well. Perhaps the most impudent of all the contentions urged by the manufacturer of spurious goods is that of a firm which exported a large quantity of what was described as a well-known drug. This was proved to be simply a cheap substitute for the genuine balsam, but it was urged that, medicinally speaking, it served the same purpose as the genuine article, so that there was no harm in calling it so! In the case also of the spurious balsam, it was allowed to pass on the payment of penalties and the alteration of the label.

It is probable, however, in this, as in the other cases cited, in which fraudulent goods were allowed to pass on these terms, that the inelasticity of the Act itself is more to blame than the Customs officials; and if this is so, it only demonstrates with added force the crying need which exists for an Adulteration Act for India on the lines of the English Food and Drugs Act.

THE JAPANESE BREWING INDUSTRY.

Bd. of Trade J., Dec. 1896, 729.

The chief expert of the Yebisu Beer Brewing Co. has been sent to Germany for two years to study the condition of the German brewing industry with its latest improvements.

The brewers of Japan have not only succeeded in nearly putting a stop to the import of most malt liquors into Japan, but now export their produce to China and Singapore, and even as far as Bombay. In fact, the supply is hardly adequate to meet the growing demand. There are at present only four breweries in Japan carrying on business on a large scale, namely, the Kirin (Japan Brewery Co., Ltd.), the Asahi, the Sapporo, and the Yebisu. The output of these four breweries does not exceed 50,000 koku* per annum. Compared with the yearly output of saké, amounting to 1,000,000 koku, the quantity of beer produced in Japan does not exceed $\frac{1}{20}$, while from the point of view of the alcohol contained in the two, the ratio falls to 1 in 300. Consequently, if the steady increase in the consumption of Japanese beer in foreign markets be taken into consideration, the quantity of beer brewed in Japan may be increased by 10 or even 20 times the amount now manufactured. Of the various fermenting industries of Japan, beer-brewing is generally admitted to be one of the most profitable, and this even though malt is imported from abroad. The profits would, therefore, be very much greater were this material produced at home. The Yebisu Beer Co. is paying earnest attention to this point, and is manufacturing malt experimentally from German barley with the latest appliances available. It was for the purpose of investigating this important branch of the industry that the company decided to despatch its expert to Germany. Success in producing malt in Japan would mark an epoch in the history of beer-brewing in the country. It is said that the Yebisu Co. has decided to establish another brewery capable of producing 16,000 koku, so that, on the completion of this scheme, the total output of the company will be increased to about 60,000 koku. For this purpose the Company's capital is to be increased from 600,000 yen to 1,300,000 yen.

* Koku = 39.7 galls.

THE TANNING INDUSTRY OF INDIA.

Bd. of Trade J., Dec. 1896, 730.

According to an article in *Capital* (Bengal), the tanning industry in British India has now assumed important dimensions. The value of last year's exports of tanned skins and hides by sea to foreign countries aggregated over four crores, indicating, after a steady annual expansion, an increase of 42 per cent. within the past five years. The trade is one in regard to which there seem to be prospects of still further development on a large scale. In the case of finished leather goods, a very general impression has hitherto prevailed that English leather was infinitely superior to the Indian article, and to a great extent Government and private purchasers have been content to pay the considerably higher cost of British-made articles in the belief that they were getting relatively better value for their money. This, however, can no longer be accepted as a general rule, practical experience in numberless instances proving the contrary.

The foremost leather manufacturers in India keep well abreast of the time, and have shared in all that the application of modern science has done for the tanning industry. Recent comparative experiments undertaken in England between artillery harness made of Indian leather turned out in the Government harness and saddlery works at Cawnpore, and the same made in England of home-produced leather, proved the former to be the stronger; and, presumably, there could hardly have been a severer test. Cawnpore is the centre, no doubt, of a great leather industry, but one which is probably only in its infancy as yet. Operations locally are, in the meantime, apparently confined to the production of material sufficient in quantity to meet the demands for manufactured articles. In the foreign export trade in tanned hides and skins, Madras stands far to the front; five-sixths of the total exports from India being shipped from that seaport, the tanned goods of the Southern Presidency finding, it is said, a better market in Europe than any other province. Other provinces, in fact, export hides and skins largely to Madras, but it is not likely that the advantage which that Presidency has hitherto enjoyed in the superior descriptions of tanning bark produced in Southern India will long survive the recent introduction of other tanning materials which, as far as reagents are concerned, place all provinces on a par.

NEW PETROLEUM AND OZOKERITE FIELDS IN RUSSIA.

Eng. and Mining J., Dec. 5, 1896, 538.

For many years petroleum and ozokerite have been known to exist in the island of Cheleken, in the Caspian Sea. According to a recent German report, the oil is forced to the surface by numerous springs of hot sulphur water (102° F.), and accumulates in wells dug by the Turcomans. In 1876 the first attempt in the direction of a rational exploitation was made by T. Palankowski, a well-known oil operator of Baku. The attempt, however, did not result successfully, because the upper sands were almost exhausted by the diggings of the Turcomans. The operations commenced by Nobel Brothers, in 1881, were also stopped after a short time, partly because of lack of labour, as the Turcomans refused to work; partly on account of the intention at that time to concentrate the production and manufacture of petroleum on the Apsheron peninsula. This field was then forgotten until quite recently. The attention of prospectors has been called again to the island, especially by the authorities of the Transcaucasian territory, who were looking for a cheap liquid fuel for the Transcaucasian Railway, and caused the resumption of operations on the island, which were accompanied by favourable results. The firm of Nobel Brothers has now resumed operations. Analytical tests made in the laboratory of the Technical Committee of Baku have shown that the crude oil of Cheleken Island possesses very peculiar properties. It is of thick consistency at 9° C., like salve, and becomes solid at a little below 0° C. Its water content is hard to eliminate, and this circumstance proves a serious obstacle in the distillation. Its specific gravity at 15° C. is 0.868, the flashing point 51.5° C.

The residue possesses at ordinary temperature, 22·5°, the consistency of salve or jelly, a specific gravity of 0·900, and can be worked up directly to vaseline. Another characteristic of this oil is its high content of paraffin, amounting to 5·5 per cent., which, after being refined, furnished about 3 per cent. of white amorphous paraffin wax.

PRODUCTION, DELIVERIES, AND EXPORTS OF SULPHATE OF AMMONIA, 1890 to 1895.

J. Gas Lighting, 68, Dec. 1, 1896, 1073.

Messrs. Bradbury and Hirsch's "Review of the Sulphate Market for 1895" gives the production, exports, and home consumption, &c. of sulphate for the past 10 years.

	1890.	1891.	1892.
Produced (tons).....	134,000	143,000	150,000

—Bradbury and Hirsch.

From the table it will be seen that there is an increased production of 11,000 tons as compared with 1894, which is made up as follows:—Gas works, 2,500 tons; iron works, 1,500 tons; and shale works, 7,000 tons; total, 11,000 tons. This shows that the bulk of the extra production was from Scotland—brought about probably by the immunity from labour troubles. Compared with production, the exports show a slight falling off since 1893. The increased production from coke ovens in Germany may account for the decrease in the exports to that country, as it is a noticeable fact that Germany, Holland, and Belgium show a falling off of some 5,000 tons as compared with 1894. Taking the year 1895 as a whole, however, the exports to the Continent show an increase of about 9,000 tons over the previous year; but the home consumption, which has been on the decline since 1891, fell 2,000 tons short of 1894.

CORSICAN MINES.

Ch. of Commerce J., Nov. 1896, 203.

The British Consul says that the antimony mines of the Cape Corse are the only mines at work. They are the Luri mine, owned in England, and the Meria and Ursa mines, owned locally. They produced between them an average per annum during the last five years of 1,300 tons of ore containing 45 per cent. of metal, and 300 tons of ore containing 30 per cent. of metal. Almost all this goes to London to be smelted, and is used for making star antimony, chiefly used in alloys and type-metal. Japan, being a large producer, has been able to undersell Corsican and all European antimony ores owing to the low price of silver giving such an enormous advantage on

exchange. The result is a reduction in output in Europe, only the best mines, such as the Corsican, being able to compete with Japan. With silver rising in value somewhat, the prices for ores are improving, and at the present moment demand for Corsican ores exceeds the production. With the advance in value of copper more attention is being paid to the copper lodes which undoubtedly exist, but have been little proved. A local company is now opening up an important deposit of pyrites carrying 6 per cent. of copper and 45 per cent. of sulphur, and will shortly be turning out 500 tons monthly. Another mine, which has not been worked for years, is about to be offered at public sale by Government, on the advice of the chief engineer of mines that it is too important to remain in the hands of concessionaires who do not work it. The Consul adds that he will be happy to supply full details of these and other mines to any persons applying to him.

THE TIN PRODUCTION OF BOLIVIA.

Eng. and Mining J., Nov. 21, 1896.

Through the courtesy of Sr. F. G. Grauert, of Sucre, we have received the following statement, giving the exports of tin from Bolivia to England for eight years past. These exports practically represent the production, and the figures are taken from the Bolivian Government reports, the quantities being in metric tons.

Exports of Tin from Bolivia.

Year.	Barra.	Barrilla.	Fine.	Bars.
	Tons.	Tons.	Tons.	Tons.
1888	440	1,120	923	1,363
1889	590	1,229	999	1,389
1890	565	1,087	1,006	1,664
1891	663	1,379	896	1,559
1892	1,076	2,681	2,743	2,819
1893	1,362	2,380	1,547	2,909
1894	1,305	3,350	2,199	3,482
1895	1,612	4,824	2,485	4,997

The Bolivian ores, as a rule, are very rich, some of the best being reported as carrying 65 per cent. metal. This far exceeds those of any other country. It will be seen that in the last four years there has been a large increase.

NEW SOUTH WALES DRUG TRADE.

Chem. and Druggist, Dec. 5, 1896, 814.

A lengthy and interesting German consular report on the trade of New South Wales states that the principal pharmaceutical articles imported into the colony, in addition to crude drugs, are acetic, sulphuric, and tartaric acids, bicarbonate of soda, caustic soda, soda ash and crystals, cream of tartar, glycerine tinctures, and extracts. The value of the importation in 1895 was 272,974*l.*, an increase of 8,514*l.* upon the preceding year. As a rule, fine drugs and chemicals are imported direct from Germany, while the staple articles are from Britain. In 1895 Germany supplied drugs to the value of 7,660*l.*, acetic acid 979*l.*, tartaric acid 1,315*l.*, cream of tartar 1,675*l.*, and various chemicals 2,019*l.* These figures show that the direct imports from Germany are still very small, for the total value of importation was as follows:—Drugs, 138,572*l.*; cream of tartar, 26,107*l.*; alkalis, 26,073*l.*; acids, 20,259*l.* The importation of paints and colouring materials shows a considerable decrease, but the German share therein is insignificant, and amounts to only a few dry colours and common brushes. The market in photographic materials, especially cameras and dry plates, is entirely in British and American goods, and the German Consul states that for the present it would seem to be hopeless to expect interference with this trade, especially as the articles now supplied are of good workmanship, and low in price. On the other hand, photographic chemicals, albuminised paper, and mounts are mostly of German origin. The total import of photographic articles amounted to 15,756*l.* in value, of which about 20 per cent. came from Germany.

DISCOVERY OF ICHTHYOL.

Chem. and Druggist, Dec. 5, 1896, 813.

Up to the present we believe that the raw material for ichthyol, the pharmaceutical product distilled from fossilised fish-remains, has only been found in the Tyrol. Recently, however, another ichthyol deposit has been discovered on the coast of the Adriatic. The bituminous product is said to yield on an average 18 per cent. of pure ichthyol.

THE RUSSIAN QUICKSILVER INDUSTRY.

Chem. and Druggist, Dec. 5, 1896, 813.

The quantity of quicksilver exported by the mines of the firm of Auerbach and Co. at Nikotovka, in the government of Ekaterinoslav, in the course of last year amounted to 10,706 bottles, which went to various European countries, China, India, and to the Transvaal. For consumption in Russia itself 1,595 bottles were sold. The output is steadily increasing, and is likely to be considerably larger this year than last.

THE MARKET FOR GAS RESIDUALS.

W. E. Price. J. Gas Lighting, 1896, 68, 958-961.

This paper, which is accompanied by well compiled tables and diagrams, gives a review of the course of the residuals market over the last four years.

Coke.—Since the middle of 1894 the market has been and is still in a very unsatisfactory condition, the demand having been below the average of previous years owing to climatic conditions.

Coal Tar.—This has greatly improved in value since 1893, at which period it had an average value of 13s. 7½d. per ton, whereas the average value of nine months this year has been 21s. 6½d. This increase has been brought about by the rise in the value of pitch, benzene, and naphthalene.

Pitch.—This material advanced in price during 1894-5, and has kept steady this year at an average value for nine months of 32s. 7½d. per ton.

Benzene.—A notable rise has taken place this year after a period of very low market value. At Michaelmas 1895 "90 per cent. benzol" was 11½d. per gallon; at Michaelmas 1896 it was 3s. 9½d. The low price in 1894-5 offered an inducement to apply it to gas-enriching purposes, and large quantities were consumed with great success.

Anthracene.—This product has been fairly steady in price, with a slight decline, from 1s. per unit per cwt. in 1893 to 10½d. at Michaelmas 1896.

Naphthalene.—This material has been in good demand, and has had an average value this year of 55s. 6d. per ton.

Sulphate of Ammonium.—The average price in 1893 was 12l. 11s. 1d. per ton; in 1894, 13l. 6s. 5d.; in 1895, 9l. 15s. 9d.; and in 1896 (nine months), 8l. 1s. 8d. From a diagram showing the annual values from 1867 to 1896, also the equivalent value of sodium nitrate since 1880, it appears that a comparatively steady period for "sulphate" prevailed between 1886 and 1892, the value being 11l. to 10l. per ton. This was succeeded by a considerable rise and fall in the following four years. Nitrate, on the other hand, has experienced a downward tendency since 1895 from 10l. to 8l. per ton. There is not much evidence to show that the one has any influence on the other, or at any rate to which the influence belongs. The reduction in sulphate is due to over-production and the circumstance that the competition with other nitrogenous materials in the market for artificial manures has been very severe of late.—D. B.

SULPHUR IN THE UNITED STATES.

Eng. and Mining J., Dec. 12, 1896, 552.

The recent rapid increase in the price of sulphur through the operations of the Sicilian combination, and the probability that prices can be kept up to or at least near the present level, has turned attention very generally to the possibilities of an extended use of pyrites in the manufacture of sulphuric acid, or to obtaining new supplies of sulphur. The first thing, of course, is to secure the raw materials, and the conditions now present an opportunity to the owners of deposits to make a market for their product such as has probably never before existed. A few weeks ago, brimstone

was selling at 26 dols. and 28 dols. per ton, an advance of from 50 to 60 per cent. over the price of last July; and even now the price is 22 dols. to 24 dols. per ton. There are a number of deposits of pyrites in the South, which could furnish a supply, but unfortunately most of them are so located that the expense of transportation from the mines is very heavy. Thus it is now a fact that the fertiliser factories of Atlanta, Ga., have used imported pyrites, although there are large deposits within 150 miles of them; but these deposits are 40 miles from a railroad, and the expense of hauling that distance over mountain roads has been greater than the cost of freight across the ocean. A further objection to the use of pyrites in many cases is the expense of altering plants, or perhaps of putting in new furnaces, which might be necessary.

The present conditions certainly present a favourable opportunity for the development of our own deposits of sulphur, which has heretofore proceeded very slowly. It seems probable that if the Sicilian operators hold together and succeed in keeping up the price, an increase in domestic supplies, both of sulphur and pyrites, may be expected. In our market columns last week reference was made to the Texas sulphur deposits, which are believed to be of great value, and to the possibility of an early beginning of work upon them. It is to be hoped that the company referred to will be successful in exploiting its property, and that Texas brimstone will soon be a recognised factor in the market.

APPLICATIONS.

- 25,794. J. S. Raworth. Improvements in apparatus for compressing air and other gases. Nov. 16.
 25,842. J. G. Chamberlain and J. Weddell. Improvements in evaporative surface condensers. Nov. 17.
 26,112. J. Critchlow and T. Shore. Improvements in filter presses. Nov. 19.
 26,141. F. C. Weedon. Improved means for determining the expansion of solids. Nov. 23.
 26,705. G. Rose. Improvements in portable noiseless furnaces and oil-gas apparatus for welding, puddling, and smelting, steam-raising, humidifying, and glass manufacturing; also applicable for cooking stoves and hot-water heating apparatus. Complete Specification. Nov. 25.
 26,937. J. W. Hall. Certain improvements in or connected with regenerative furnaces. Nov. 27.
 27,009. P. H. Rosenkranz. Improvements in diaphragms. Nov. 27.
 27,177. J. Grossé. See Class XVII.
 27,494. E. Riepe and G. Oppermann. Improvements in regenerative furnaces. Complete Specification. Dec. 3.
 27,778. H. Niewerth. Improved manufacture of articles and vessels for holding and resisting acids and alkalis, and for other purposes. Dec. 5.
 27,969. F. P. Candy. Improvements in apparatus for the removal of deposit from settling tanks. Dec. 8.
 27,989. F. M. Ashby. Improvements in sterilising apparatus. Complete Specification. Dec. 8.
 28,072. J. Kent. An improvement in the manufacture of thermometers. Dec. 8.
 28,289. S. Sherratt and W. A. Richards. Improvements in the method of and apparatus for filtering, washing, and drying crystalline, granular, and other materials. Dec. 10.
 28,411. S. Straker. Improvements in apparatus for evaporating water containing salts and calcareous matter, and in heating furnaces for removing the incrustations from the coils of such evaporating apparatus. Complete Specification. Dec. 11.

COMPLETE SPECIFICATIONS ACCEPTED.*

1895.

- 22,713. J. Y. Johnson.—From The Verein Chemischer Fabrik. Apparatus for drying superphosphates and the like. Dec. 2.
 22,900. W. P. Abell. Centrifugal machines for drying sugar and other granular substances. Dec. 2.
 23,385. G. Platt. Metallurgical furnaces. Dec. 9.
 23,664. E. Ljungström. Evaporating or heating apparatus. Dec. 9.
 24,337. L. A. Chevalet and W. Boby. Apparatus for heating and purifying water. Nov. 25.
 24,499. G. P. Wallis. Hydraulic presses for expressing oil from seeds and such like. Nov. 25.
 24,835. W. Raydt. Apparatus for filtering liquids and impregnating the same with gases. Dec. 9.

1896.

1112. D. A. Quiggin. Evaporators, condensers, and the like. Dec. 2.
 1177. C. S. Meacham. New or improved apparatus for separating bodies of different specific gravity when immersed in a liquid. Nov. 25.

3572. S. S. Bromhead.—From Dierks and Mollmann. Sterilising apparatus. Dec. 9.

1241. C. G. J. Moller and P. Pfeifer. Drying apparatus. Dec. 16.

18,717. A. J. Boulton.—From C. A. Macdonald. Method and apparatus for cooling, purifying, and drying air for chilling and freezing purposes. Nov. 25.

19,405. E. Dieble. Improved continuous counter-current saturation apparatus. Nov. 25.

20,982. J. Van Ruymbeke and W. F. Jobbins. Distilling apparatus. Nov. 25.

22,060. W. F. E. Casse. Apparatus for heating, pasteurising, and cooling liquids. Nov. 25.

23,991. L. Sterne.—From The De la Vergne Refrigerating Machine Co. Refrigerating and ice-making apparatus. Dec. 2.

II.—FUEL, GAS, AND LIGHT.

APPLICATIONS.

- 25,762. M. Arndt. Gas-absorbing apparatus for ascertaining the quantity of a particular gas in a gaseous mixture. Nov. 16.
 25,827. E. Sfriwan. Improvements in the method of and means for binding mantles for incandescent lights. Nov. 17.
 25,884. M. M. Oppenheimer. Improvements in mantles for use in incandescent lighting. Nov. 17.
 25,887. F. J. Collin. Improvements in or relating to coke furnaces. Complete Specification. Nov. 17.
 26,041. E. Edwards.—From R. Turr. Improvements in apparatus for applying acetylene gas to the purpose of incandescent lighting or heating. Nov. 18.
 26,121. W. H. Royle. Apparatus and method for generating and producing gases at pressure for use in motors. Nov. 19.
 25,167. B. Puchmüller. An improved process for the manufacture of fluid for impregnating bodies or suitable fabrics, threads, fibres, or the like, for illuminating or lighting purposes. Complete Specification. Nov. 19.
 26,191. E. T. Zohrab. Improvements relating to the production of peat charcoal, and to apparatus therefor. Nov. 19.
 26,228. T. Mitchell. Improvements in or relating to fuel. Nov. 20.
 26,261. J. C. Mewburn.—From F. G. Bates. Improvements in and in apparatus for the manufacture of combustible gas, including illuminating gas in motor engines driven by such gas, and in steam generators. Complete Specification. Nov. 20.
 26,284. F. O. Prince. Improved manufacture of hydrogen gas and apparatus therefor. Nov. 20.
 26,304. R. Van de Ghinste. Improvements in means for incandescence gas-lighting. Complete Specification. Nov. 20.
 26,359. J. M. Somerville. Improvements in the manufacture of illuminating gas. Nov. 21.
 26,363. R. E. Middleton. Apparatus for improving the quality of hydrocarbon oils. Nov. 21.
 26,376. W. P. Thompson.—From La Société Egrot and Grange. An improved apparatus for producing acetylene gas. Nov. 21.
 26,468. F. O. Prince. Improved apparatus for generating carburetted hydrogen. Nov. 23.
 26,509. A. Wilson. Improvements in apparatus for cleaning gas. Nov. 23.
 26,516. G. Treseureuter. Method and apparatus for producing gas from liquid combustible materials. Nov. 23.
 26,618. J. F. Duke. Improvements in the manufacture of mantles or incandescing bodies for incandescent gas lamps. Nov. 24.
 26,647. R. Kuhn. Improvements in acetylene gas apparatus. Filed Nov. 24. Date applied for, April 27, 1896, being date of application in Switzerland.

26,732. J. Worthington. For improvements in apparatus and method for increasing the illuminating power and heating purposes of gas. Nov. 25.

26,784. R. Moll and A. Palmer. A new or improved method of manufacturing incandescent mantles or caps for gas and other burners. Complete Specification. Nov. 25.

26,870. J. Kranz, I. Saxl, and A. Wallesz. Improvements in apparatus or lamps for the generation of acetylene from calcium carbide. Nov. 26.

26,873. W. B. Hartridge. An improvement in fuel blocks applicable as fire-lighters. Nov. 26.

26,897. J. Vaughan-Sherrin. Improvements in and connected with apparatus for the production and utilisation of acetylene gas. Nov. 26.

27,085. S. D. Gillet, G. Forest, and J. E. O. Bocande. A new or improved arrangement of apparatus for lighting by acetylene gas. Complete Specification. Filed Nov. 28. Date applied for, May 30, 1896, being date of application in France.

27,086. S. D. Gillet, G. Forest, and J. E. O. Bocande. A new or improved burner for lighting by acetylene or other gases rich in carbon. Complete Specification. Filed Nov. 28. Date applied for, May 30, 1896, being date of application in France.

27,137. J. A. Cumine and E. J. Dexter. An improved illuminant. Nov. 30.

27,194. A. J. de Pimental Hargreaves. Improvements in the manufacture of acetylene gas and in apparatus therefor. Nov. 30.

27,212. J. Wetter.—From G. Meyer. Improvements in apparatus for generating acetylene gas. Nov. 30.

27,338. B. T. L. Thomson. Improved process and apparatus for the manufacture of acetylene gas. Dec. 1.

27,457. S. Braun and H. Schlesinger. Process and apparatus for producing a new lighting gas. Complete Specification. Dec. 2.

27,574. E. Gossart and H. Chevallier. Improvements in or relating to means for regulating the production of acetylene gas and in lamps therefor. Filed Dec. 3. Date applied for, May 5, 1896, being date of application in France.

27,697. H. H. Lake.—From V. Hanotier and G. Hostelt. Improvements in acetylene gas generators. Dec. 4.

27,744. A. Kiesewalter. Process of manufacture of a carbide which, by its decomposition by water, produces acetylene gas. Filed Dec. 5. Date applied for, May 6, 1896, being date of application in Belgium.

27,945. T. Holmes, G. S. Holmes, R. W. Stewart, and R. T. Barnes. An improved method of and apparatus for producing and burning inflammable gas. Dec. 8.

28,083. E. J. Feuillette. Improvements in apparatus for generating acetylene gas. Dec. 8.

28,101. J. A. Sinclair. Improved means for lighting by electricity and incandescence. Dec. 8.

28,206. T. R. Fowler. Improvements in and connected with acetylene gas generator, purifier, and container. Dec. 10.

28,265. E. Barker. The incandescent fire ball. Dec. 10.

28,279. Sir C. S. Forbes, Bart. Improved apparatus for automatically regulating the supply of liquid fuel. Dec. 10.

28,280. Sir C. S. Forbes, Bart. Improved apparatus for vaporising and burning liquid fuel. Dec. 10.

28,290. F. V. C. Brokk. An improved vaporiser for liquid combustibles for incandescent lighting or heating purposes. Dec. 10.

28,302. A. J. Bonlt.—From L. Serres. Improvements in or relating to the generation of acetylene gas, and in apparatus therefor. Dec. 10.

28,425. H. T. Marks and J. T. Todman. Improvements in apparatus for generating gases for illuminating and other purposes. Dec. 11.

28,432. T. Holmes, G. L. Holmes, R. W. Stewart, and R. T. Barnes. An improved method of and apparatus for producing inflammable gas. Dec. 12.

COMPLETE SPECIFICATIONS ACCEPTED

1895.

24,008. B. Barriere. Preparation and production of bodies for use in what is known as incandescent gas lighting. Dec. 2.

1896.

361. H. Bower. Improvements in methods of separating the cyanogen compounds from gas liquor or other solutions containing cyanogen compounds. Dec. 16.

1351. J. Hawley. Construction of wood grids for gas purifiers. Dec. 2.

1521. N. T. M. Wilshire.—From D. Little. Improvements in incandescent gas or oil lighting. Dec. 2.

1841. P. Steins. Incandescent mantles. Dec. 16.

2269. J. Moeller. Incandescent gas lamps. Dec. 16.

3560. A. Quentin. Apparatus for burning liquid fuel. Dec. 9.

18,207. R. P. Pictet. Manufacture of acetylene, and apparatus therefor. Dec. 9.

18,208. R. P. Pictet. Purification of acetylene, and apparatus therefor. Dec. 2.

23,079. O. Streiber and P. Kiefer. Factory fuel. Dec. 2.

23,812. R. Haddan.—From H. Colberg. Apparatus for the automatic production of acetylene gas. Dec. 2.

24,809. A. Schoenemann. Drying peat. Dec. 16.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

APPLICATIONS.

26,771. G. Schultz. An improved process for obtaining benzol and similar aromatic hydrocarbons. Nov. 25.

27,527. G. B. Ellis.—From La Société Chimique des Usines du Rhone, anciennement G. P. Monnet et Cartier. Improvements in the manufacture of preparations of guaiacol, creosote, and other higher phenols. Dec. 3.

IV.—COLOURING MATTERS AND DYES.

APPLICATIONS.

25,725. I. Levinstein and Levinstein, Lim. Production of a new colour base and of colouring matters therefrom. Nov. 16.

26,019. Read, Holliday, and Sons, Lim., J. Turner, and H. Dean. Improvements in the production of sulpho acids and colouring matters therefrom. Nov. 18.

26,020. Read, Holliday, and Sons, Lim., J. Turner, and H. Dean. Improvements in the production of sulpho acids and colouring matters therefrom. Nov. 18.

26,139. H. E. Newton.—From The Farbenfabriken vormals F. Bayer and Co. The manufacture or production of chemical compounds of the aromatic series. Nov. 19.

26,183. J. Y. Johnson.—From The Badische Anilin und Soda Fabrik. Improvements in the preparation of colouring matters. Nov. 19.

26,210. W. H. Claus, A. Ree, and L. Marchlewski. Production of new azo colouring matters. Nov. 20.

26,666. A. Zimmermann.—From The Chemische Fabrik auf Actien vormals E. Schering. The manufacture of isomeric unsymmetrical acetonealkamines and acetyl derivatives therefrom. Nov. 24.

26,972. L. D. Huguenin and Co. Manufacture of colouring matter of the series of oxazines. Nov. 27. Date applied for, April 27, 1896, being date of application in France.

27,147. A. Ashworth and J. Burger. Improvements in the production of colouring matters. Nov. 30.

27,660. A. Zimmermann.—From The Chemische Fabrik auf Actien vormals E. Schering. The production of aminopiperidines and of acetonealkamines therefrom. Dec. 4.

27,775. J. Ville. New red colouring matters of the triphenylmethane series and the method of producing the same. Filed Dec. 5. Date applied for, Dec. 2, 1896, being date of application in France.

27,896. O. Imray. — From The Farbwerke vormals Meister, Lucius, and Brüning. Manufacture of basic disazo dyestuffs. Dec. 7.

28,499. A. G. Green. Improvements in the production of paranitraniline red. Dec. 12.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

23,523. I. Levinstein and Levinstein, Lim. Manufacture or production of new azo colouring matters. Dec. 9.

24,193. G. B. Ellis. — From La Société Chimique des Usines du Rhone, anciennement G. P. Monnet, and Cartier. Production of para-nitro-phenol and ortho-nitro-toluene-para-sulphonic acid. Nov. 25.

1896.

2446. S. Pitt. — From L. Cassella and Co. Manufacture of azo dyes. Dec. 16.

2765. W. H. Clans and A. Ree. The production of blue colouring matters. Dec. 9.

3000. O. Imray. — From The Farbwerke vormals Meister, Lucius, and Brüning. Manufacture of colouring matter from substituted fluoresceines. Dec. 16.

3028. S. Pitt. — From L. Cassella and Co. Production of polyazo dyestuffs. Dec. 16.

V.—TEXTILES, COTTON, WOOL, SILK, Etc.

APPLICATIONS.

25,789. A. V. Newton. — From A. Nobel and R. W. Strehlenert. Improvements in the manufacture of artificial silk or other fibre. Nov. 16.

25,913. D. Scott. The manufacture of new or improved garments and articles from a new or improved proofed fabric. Nov. 17.

26,024. H. K. Tompkins. Improvements in the manufacture and treatment of artificial fibres. Nov. 18.

26,485. J. S. Brown. Improved process and apparatus for preparing vegetable fibres for textile purposes. Nov. 23.

27,050. K. T. Sutherland and G. Esdaile. Improvements connected with the degumming, cleansing, and treatment of vegetable leaf and stalk and animal fibres. Nov. 28.

27,483. H. C. Longsdon. Improved yarn-drying apparatus. Dec. 3.

27,484. H. C. Longsdon. Improved means or apparatus applicable for use in the drying of wool and other fibrous substances. Dec. 3.

27,679. F. Morane, jun. Improvements in apparatus for the production of artificial silk. Dec. 4.

28,376. H. Giesler. Improvements in the manufacture of mixed or parti-coloured fabrics. Dec. 11. Date applied for, June 3, 1896, being date of application in France. Dec. 11.

COMPLETE SPECIFICATIONS ACCEPTED.

1896.

1370. F. N. Turney. Apparatus for degreasing and cleansing wool, cotton waste, and like fibrous material. Nov. 25.

8323. C. M. White. — From The Electro Waterproofing and Dye-Fixing Co. A new or improved process of electrically treating fabrics for waterproofing and other purposes. Dec. 16.

VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

APPLICATIONS.

25,502. P. Jensen. — From M. Petzold. Improvements in apparatus for dyeing and bleaching warp, cop, twist skeins, and loose material. Nov. 17.

26,495. A. Vogelsang. Improved process for treating dry materials (more particularly fibrous substances) with liquid. Complete Specification. Nov. 23.

27,218. E. Thomas. Improvements in circulating dyeing apparatus. Complete Specification. Nov. 30.

27,409. A. Leven. New process for dyeing a thread in different colours. Dec. 2.

27,742. H. W. Kearns and J. Barnes. Improvements in the production of fast colours upon vegetable fibre. Dec. 5.

28,266. A. F. B. Gomess. Improvements in bleaching textile vegetable fibres, yarns, and fabrics. Dec. 10.

COMPLETE SPECIFICATION ACCEPTED.

1896.

2844. A. H. Brownlow and J. Stansfield. Method of dyeing. Dec. 9.

VII.—ACIDS, ALKALIS, AND SALTS.

APPLICATIONS.

25,740. T. Twynam. Improvements in the production of caustic alkalis and alkaline carbonates. Nov. 16.

25,938. P. G. W. Typke. Improvements in the manufacture of phosphorus compounds. Nov. 17.

26,423. H. Maxim. An improved method and apparatus for the production of calcium carbide, applicable also to the reduction of metals from their oxides and to analogous purposes. Nov. 21.

26,508. C. Schwarz and A. Weishut. Process of manufacturing muriatic acid or chlorine and chloride of potassium from calcium chloride and chloride of magnesium and other suitable chlorides. Nov. 23.

26,824. F. Dresser. Improvements in the manufacture of carbide of calcium and the like. Nov. 26.

26,837. A. J. Bambridge and G. Weddell. An improved method of manufacturing bicarbonate of soda. Nov. 26.

26,889. F. J. Seyfried. Improvements in the preparation of caustic soda solution from soda residues. Complete Specification. Nov. 26.

27,769. E. Dyson. Improvements in apparatus for concentrating sulphuric and other acids. Dec. 5.

28,163. G. Sisson. Improved method of and process for producing carbonic acid gas. Dec. 9.

28,199. H. H. Lake. — From C. Pieper. An improved method or process of treating substances containing nitrogen for the manufacture of ammonia. Complete Specification. Dec. 9.

28,294. E. A. Goddin and R. Lees. An improved process and apparatus for obtaining common salt and other like salts from their solutions. Dec. 10.

28,322. T. Twynam. Improvements in the recovery of ammonia from producer gas, blast-furnace gas, and other gases. Dec. 11.

COMPLETE SPECIFICATIONS ACCEPTED.

1896.

335. H. R. Angel. Manufacture of caustic soda, carbonate of soda, and sulphide of sodium. Nov. 25.

20,290. J. Walter and C. Lehmann. Nitric acid regenerator. Dec. 16.

21,572. M. P. E. Letang. Process for the treatment of carbide of calcium. Nov. 25.

VIII.—GLASS, POTTERY, AND ENAMELS.

APPLICATIONS.

26,046. D. Laffan, G. Moore, and T. J. Glynn. Improvements in apparatus for forming glass bottles or other glass ware. Nov. 18.

26,212. W. Illingworth. Improvements in thimbles for the purpose of supporting pottery ware while being fired in ovens and kilns. Nov. 20.

26,374. T. W. Simpson and W. H. Bradshaw. Improvements in the manufacture of glass bottles and in apparatus for the same. Nov. 21.

26,890. W. Preston. Improvements in glass-annealing furnaces or leers. Nov. 26.

26,937. P. B. W. Kershaw. An improved method and means for the mechanical formation of bottles or other articles in glass. Nov. 27.

27,200. W. Brothers. Improvements in the manufacture of plaster of Paris and other useful products. Nov. 30.

27,828. J. Morton. A new means and method of enamelling or glazing bricks, tiles, and the like. Dec. 7.

28,146. W. Stockton. An improvement treating with the process of decorated ceramics. Dec. 9.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

1794. J. W. Ormrod. Improvements in kilns for use in the manufacture of bricks, terra-cotta goods, tiles, and the like. Dec. 2.

23,814. W. H. Godwin and T. Pickerill. Improvements in slabbing tiles, mosaics, and other similar appliances. Dec. 16.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

APPLICATIONS.

25,876. W. White. Improvements in treating clay. Nov. 17.

25,880. A. H. van der Vygh, H. van der Vygh, and G. van der Vygh. An improved fire-proof artificial stone. Complete Specification. Nov. 17.

26,306. G. Scott. The improved concrete building construction. Nov. 21.

26,792. H. Brockhues. Process for manufacturing a material for covering walls and floors. Nov. 25.

26,847. J. J. Moffat. Improvements in connection with fireproof floors, ceilings, walls, and partitions. Nov. 26.

27,200. W. Brothers. See Class VIII.

27,648. A. Taylor. Improvements in the manufacture of artificial stone for building, paving, and other suitable purposes. Dec. 4.

27,835. C. Musker and A. Musker. Improvements in or connected with the manufacture of artificial stone. Dec. 7.

27,975. S. R. Thompson. A composition or cement for making pipe and other joints. Dec. 8.

28,291. E. Edwards.—From C. J. R. Le Mesurier. An improved composition or cement for making artificial mill stones, grind stones, and the like. Dec. 10.

28,317. J. Ripley. A hollow brick for ordinary building purposes. Dec. 11.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

23,018. E. Coulon and J. J. Defalque. Manufacture of artificial stones. Nov. 25.

24,967. M. Hoeft. Production of marble-like stucco or plaster-work suitable for walls, ceilings, and the like. Dec. 16.

1896.

68. W. R. Taylor. Apparatus for burning cement-making materials, lime, chalk, and the like, and the obtaining therefrom of carbonic acid gas. Dec. 16.

1408. G. L. Falconar. Manufacture or production of blocks or slabs for use for flooring, paving, or in step or staircase or wall construction, and for analogous purposes. Dec. 2.

2451. D. J. J. Froment. Treatment of marble and similar stone. Dec. 16.

2614. F. W. Maxwell and W. Beer. New or improved manufacture of artificial stone for building, decorative, and other purposes. Dec. 16.

2843. H. Simmonds and J. Delaney. Kilns or furnaces applicable for burning lime, cement, and other minerals. Dec. 9.

6232. F. L. Schauermaun and J. S. Cowper. Composition for use in imitation of or in substitution for wood. Dec. 9.

16,525. E. Selberg. New or improved building and insulating material. Dec. 9.

17,281. M. Bernstein. Process for producing artificial veined coloured marble. Dec. 16.

20,432. J. Grunhut. Manufacture of artificial stone. Dec. 16.

X.—METALLURGY, MINING, ETC.

APPLICATIONS.

25,738. C. Hornung. An improvement in the charging apparatus of blast furnaces. Nov. 16.

26,066. D. White and T. M. Simpson. An improved method and apparatus for extracting precious metals from slimes or other finely-divided material containing the same. Complete Specification. Nov. 18.

26,297. J. Campbell. Improvements in the method of and apparatus for treating refractory gold and silver and other metal-bearing ores and materials. Nov. 20.

26,412. F. Ellershausen. Improvements in and connected with the treatment of refractory lead ores. Nov. 21.

26,423. H. Maxim. See Class VII.

26,493. T. B. McGhie and E. G. Ballard. Improvements in the beds or tests of cupellation furnaces, assay cupels, and the like. Nov. 23.

26,507. C. Schwarz and A. Weishut. Process of manufacturing ferro-manganese or copper-manganese, or copper and sulphur or sulphuric acid from sulphurated iron or copper ores. Nov. 23.

26,698. T. Hampton. Improvements in the manufacture of steel. Nov. 25.

26,770. G. V. Frankish. A composite compound or alloy of steel. Nov. 25.

26,851. J. de F. Maunder. Improvements in the manufacture of zinc. Nov. 26.

26,906. T. C. Fawcett, Lim., and J. Swallow. Improvements in or relating to the treatment of purple and other ores, and by-products obtained from chemical works for the extraction of iron. Nov. 26.

27,311. G. J. Atkins. Improvements in the extraction of gold and silver by amalgamation from ores and sands containing them. Dec. 1.

27,346. J. J. Sheddock. Improvements in extracting metals from their ores and apparatus therefor. Dec. 1.

27,577. R. Appleyard. Improvements relating to the coating or permeation of substances with mercury or with amalgams, and to the use of substances thus coated or permeated in the extraction of gold and other metals from ores, tailings, and the like, by amalgamation, and for other purposes. Dec. 3.

27,776. P. Marino. Improvements in or connected with the obtaining of metals or alloys by electrolysis or hydro-electro-chemical action. Dec. 5.

27,801. C. Crocker and W. T. Lougher. Improvements in coating metal plates and other articles with lead. Dec. 5.

27,874. C. Strobrawa. Improvements in the manufacture of iron or steel. Dec. 7.

27,899. H. Imray.—From La Compagnie Anonyme des Forges de Chatillon et Commentry. Method of pouring steel ingots. Dec. 7.

27,927. A. J. Boulton.—From H. L. Sulman. Improvements in or relating to the treatment of ores. Dec. 7.

28,011. E. Manby. The vacuum treatment of steel, brass, and other alloys. Dec. 8.

28,361. M. M. Marcus. Process for making metal alloys. Dec. 11.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

23,052. H. R. Lewis and C. Gelstharp. Improvements relating to the extraction of gold and other metals from ores, tailings, slimes, and other compounds containing the same, the apparatus therefor, and to the preparation of solvents for use in such extraction. Dec. 2.

23,385. G. Platt. See Class I.

23,192. W. H. James and C. J. Norris. Extraction of precious metals from their ores. Dec. 9.

1896.

202. E. Placet. Treatment of metals and products resulting therefrom. Nov. 25.

1325. F. A. Ellis. Drawing and planishing tubes of aluminium alloy, and means employed therefor. Dec. 16.

1469. E. L. Oppermann. Apparatus for effecting the amalgamation of gold and the like metals in ores with mercury. Dec. 16.

2997. E. J. M. Servais and P. Gredt. Process for the direct production of iron and steel and other metals from their ores. Dec. 2.

9514. W. Kirkham and D. Evans. Method of casting ingots, and moulds and appliances connected therewith. Dec. 2.

XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

APPLICATIONS.

25,798. J. Greenwood. Improvements in the manufacture or production of chlorates and hypochlorites of potassium and sodium by electrolysis, and in apparatus therefor. Nov. 16.

25,799. F. W. Schneider. Improvements in the construction of electrodes for accumulators. Complete Specification. Nov. 16.

25,804. Dieffenbach. Improvements in the electrolytic production of zinc and alkalis. Complete Specification. Nov. 16.

25,965. J. P. Brooks and J. Holt. Improvements in the electro-deposition of metals. Nov. 18.

26,059. C. C. Connor. Improvements in electrodes. Nov. 18.

26,100. H. Leitner. Improvements in and in connection with the manufacture of electrodes for secondary electric batteries. Complete Specification. Nov. 19.

26,184. G. J. Epstein. Improvements in electrodes for secondary or storage batteries. Nov. 19.

26,247. A. E. McKecknie. An improved manufacture of moulded battery cells and other moulded articles. Nov. 20.

26,281. K. Klie. Improvements in or relating to the manufacture of metal sheets or strips by electro-deposition. Complete Specification. Nov. 20.

26,419. M. F. X. Fuchs. An improved primary battery. Nov. 21.

26,452. P. L. Norrington. Improvement in electric storage batteries. Nov. 23.

26,491. I. Lelestre. Improvements in and relating to electric accumulators. Complete Specification. Nov. 23.

26,737. H. Fewson. Improvements in and relating to electric batteries. Nov. 25.

26,828. J. D. Bell. Improvements in electric accumulators or storage batteries and primary batteries. Nov. 26.

27,167. C. E. O. Keenan. Improvements in electrical batteries. Nov. 30.

27,262. O. Rothmund, E. von Burgwall, and L. Offenschussl. An improved primary element with interchangeable electrodes and regenerable positive electrodes. Complete Specification. Dec. 1.

27,701. H. Leitner. Improvements in and in connection with the manufacture of electrodes for secondary electric batteries. Dec. 4.

27,812. E. Saarburger. An improved electric battery. Dec. 7.

28,043. E. M. Grant. An improvement in secondary voltaic batteries. Dec. 8.

28,139. A. Dodd. Improvement in lead accumulators. Dec. 9.

28,223. F. MacKinley, H. Brecknell, and E. M. Munro. A method of and means for decomposing stable salts and generating electricity. Dec. 10.

28,288. T. R. Canning. Improvements in anodes for the electro-deposition of nickel. Dec. 10.

28,314. R. Kennedy. Improvements in electrical storage batteries and cells. Dec. 11.

28,511. L. Lucas. Improvements in the manufacture of electric accumulators or secondary batteries. Dec. 12.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

23,459. E. Andreoli. Electro-depositing on and stripping gold from cathodes. Dec. 16.

1896.

986. J. C. Graham. Electro-deposition of metals. Nov. 25.

1401. A. A. Naville, P. A. Guye, and C. E. Guye. Electrical gas-reaction apparatus. Dec. 2.

20,077. T. F. Boland, C. J. Hubbell, and H. C. Hubbell. Primary batteries. Dec. 9.

XII.—FATS, OILS, AND SOAP.

APPLICATIONS.

25,774. W. McDonnell. Improvements in or connected with and apparatus for the manufacture of margarine. Nov. 16.

26,007. W. R. Harrison and E. Stephenson. Improvements in the method of and apparatus for brightening and clarifying crude oils. Nov. 18.

26,285. E. G. Scott. Improvements in the manufacture of soap. Nov. 20.

26,396. R. Gesell. Improved process for making soap. Complete Specification. Nov. 21.

27,263. A. Cawood. An improved preparation or composition for scouring or washing wool, woollen textiles, or any other suitable animal or vegetable fibre. Dec. 1.

27,906. F. W. Wright and The United Alkali Company, Ltd. Improvements in the manufacture and production of dry soap or soap powder. Dec. 7.

27,923. F. B. Aspinall and G. Wise. Improvements in purifying oils. Dec. 8.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

24,418. E. S. Wilson and E. Stewart. Separation and purification of colouring matter from crude cotton-seed oil. Dec. 16.

24,714. A. E. Morgans. Treatment of oleaginous and fatty substances of all kinds, and hydrocarbons, for purification and other purposes. Dec. 16.

1896.

10,955. G. Drimmond. An improved soap composition for washing flannel and the like. Dec. 9.

17,379. C. Schmidt. Processes for producing chemical combinations from raw wool fat. Nov. 25.

19,257. F. M. Sanders and The Digby Patents Company. Manufacture of soaps. Nov. 25.

22,873. J. G. Hargrave and A. Hargrave. Processes for purifying and deodorising butter and other solid fats and oils. Dec. 16.

XIII.—PAINTS, PIGMENTS, VARNISHES, RESINS, INDIA-RUBBER, Etc.

APPLICATIONS.

25,779. H. Helbing and G. Pertsch. Improvements in the preparation and application of coating and insulating materials for medical and other purposes. Nov. 16.

25,863. R. Bell. Process and method of manufacture of artificial rubber. Nov. 17.

26,015. A. Schmidt. Improved process for obtaining turpentine from wood and wood waste. Complete Specification. Nov. 18.

26,322. J. Fairlie. Improvements in the manufacture of red lead. Nov. 21.

26,548. F. Fenton. Improvements in the production of artificial gutta-percha and caoutchouc-like substances. Nov. 24.

26,695. F. H. Smith and C. Macintosh and Co., Lim. Improvements in the manufacture of rubber compounds and fabrics. Nov. 25.

26,833. R. D. Waddell and D. A. Sutherland. Improvements in the manufacture of insulating materials. Nov. 26.

26,874. F. W. Burger. A new and improved method of manufacturing white lead. Nov. 26.

27,038. J. E. Bedford and C. S. Bedford. Improvements in the manufacture of varnish. Nov. 28.

27,138. J. A. Cumine and E. J. Dexter. A process for producing carbon from asbestos. Nov. 30.

28,283. W. A. Hall. Improvements in water-paints. Complete Specification. Dec. 10.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

23,137. R. Langhans. Manufacture or production of coatings composed of oxides of the earth metals. Dec. 2.

24,546. R. Langhans. Manufacture or production of coatings composed of earthy oxides. Dec. 9.

1896.

654. E. Serullas and F. Hourant. Process of obtaining and purifying gutta-percha. Dec. 9.

2219. C. Sullivan. Production of paint. Nov. 25.

XIV.—TANNING, LEATHER, GLUE, AND SIZE.

APPLICATIONS.

25,894. Sir John Turney and J. T. Wood. A new or improved method of bating skins. Nov. 17.

25,955. E. V. Springborn. Artificial imitation leather. Nov. 18.

26,170. J. Hargreaves. Improvements in the manufacture of gelatine and glue, and in apparatus therefor. Nov. 19.

26,287. J. Pullman and E. E. Pullman. Improvements in the method of dressing chamois leather. Nov. 20.

27,410. J. J. Mann and F. Chaplet. Improvements in the treatment of skins or hides for industrial purposes. Dec. 2.

28,067. E. A. Muskett and J. B. Seammell. Improvements in or relating to the treatment of raw hides. Dec. 8.

XV.—AGRICULTURE AND MANURES, Etc.

COMPLETE SPECIFICATION ACCEPTED.

1896.

22,666. C. H. Langdale and A. W. Langdale. Treatment of ground slags intended for use as fertilisers. Nov. 25.

XVI.—SUGARS, STARCHES, GUMS, Etc.

APPLICATIONS.

27,471. R. Goernemann. A new or improved process for the manufacture of crystallised starch from maize. Complete Specification. Dec. 2.

28,188. A. J. Boulton.—From L. Jaussens and Co. Improvements in or relating to the production of sugar. Complete Specification. Dec. 9.

XVII.—BREWING, WINES, SPIRITS, Etc.

APPLICATIONS.

25,852. J. Schneible. Improvements in the manufacture of fermented liquors. Nov. 17.

26,655. C. Zimmer. Improved process for brewing. Nov. 24.

26,690. T. S. Manning. Improvements in brewing apparatus. Nov. 25.

27,477. J. Grossé. An improved evaporating or vacuum apparatus for the granulation of crystallisable liquids. Complete Specification. Dec. 3.

COMPLETE SPECIFICATION ACCEPTED.

1896.

21,118. J. Kwiatkowski. New or improved process for adding iron to beer. Nov. 25.

XVIII.—FOODS, SANITATION, Etc., AND

DISINFECTANTS.

APPLICATIONS.

A.—Foods.

26,498. W. F. E. Casse. Improvements in the Casse freezing process for preserving milk and cream. Complete Specification. Nov. 23.

26,635. P. M. Justice.—From M. W. Marsden. An improved product obtained from corn or maize stalks, and a process of and apparatus for making the same. Complete Specification. Nov. 24.

27,114. S. P. Sorenson and A. P. Heyman. An improved manufacture of artificial food for swine, cattle, and the like. Complete Specification. Nov. 28.

27,733. A. J. T. Digby. A new method of preserving meat for culinary purposes. Dec. 5.

27,735. J. Hogarth. Improvements in and relating to the treatment of alimentary substances. Dec. 5.

B.—Sanitation.

25,949. J. T. Norman. The purification and treatment of acid waters or effluents. Nov. 17.

26,148. M. F. Purcell. An improved process and means used therein for purifying and revivifying confined air for constant inhalation. Nov. 19.

26,506. H. Pape and W. Henneberg. Method and apparatus for producing fresh water from water containing salts. Complete Specification. Nov. 23.

26,667. A. Zimmermann.—From The Chemische Fabrik auf Actien vormals E. Schering. Improvements in disinfecting and in apparatus therefor. Nov. 24.

27,513. F. P. Candy. Improvements in the purification of sewage and polluted waters. Dec. 3.

28,050. E. Manville and C. von Buch. Improved method of and means for the purification and revivification of confined atmospheres. Dec. 8.

C.—Disinfectants.

26,262. L. Conz. New anti-septical composition for laundry use. Nov. 20.

COMPLETE SPECIFICATIONS ACCEPTED.

A.—Foods.

1896.

1827. M. C. A. Ruffin. Manufacture of an edible fat from cocoa or coprah oil. Dec. 9.

C.—Disinfectants.

1896.

2197. E. Hermite, E. J. Paterson, and C. F. Cooper. Preparation of electrolysed chloride solutions for disinfecting and like purposes. Dec. 16.

XIX.—PAPER, PASTEBOARD, Etc.**APPLICATIONS.**

25,986. D. Forbes. A composition for use as a substitute for ivory, bone, celluloid, and the like, applicable also to other purposes. Nov. 18.

26,045. C. Marter. Improvements in or relating to artificial ivory. Nov. 18.

26,461. J. A. Wilkinson, F. C. Wilkinson, and A. T. Wilkinson. An improved machine for softening paper. Complete Specification. Nov. 23.

27,105. H. de Gronsilliers. Improved manufacture of transfer paper for transferring designs on to ceramic and other objects. Nov. 28.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES, AND EXTRACTS.**APPLICATIONS.**

25,778. H. Helbing. Improvements in the preparation and application of menthol. Nov. 16.

25,786. A. J. Boulton.—From L. Fromm and R. Schmidt. Improvements in vegetable extracts and the method of obtaining the same. Complete Specification. Nov. 16.

25,905. G. B. Ellis.—From La Société Chimique des Usines du Rhone, anciennement G. P. Monnet et Cartier. Manufacture of a new salt of piperazine. Nov. 17.

26,078. W. B. Bishop. Improvements in the treatment of piperazine. Nov. 19.

26,350. A. J. Boulton.—From F. Fritzsche and Co. A new or improved process for the manufacture of artificial essence or essential oil of violets. Nov. 21.

26,397. H. E. Aspinall. Improvements in the manufacture of artificial camphor. Nov. 21.

27,655. G. B. Ellis.—From La Société Chimique des Usines du Rhone, anciennement G. P. Monnet et Cartier. Improvements in the manufacture of benzoic sulphimide. Dec. 4.

27,656. G. B. Ellis.—From La Société Chimique des Usines du Rhone, anciennement G. P. Monnet et Cartier. Improvements in the production of formic aldehyde vapours. Dec. 4.

COMPLETE SPECIFICATIONS ACCEPTED.

1896.

1202. J. Y. Johnson.—From Vereinigte Chininfabriken, Zimmer, and Co. The manufacture or preparation and production of new medical compounds. Nov. 25.

4991. J. Y. Johnson.—From Vereinigte Chininfabriken, Zimmer, and Co. The manufacture and production of new pharmaceutical preparations. Dec. 16.

9076. T. P. Sims and W. Terrill. Manufacture of white arsenic. Dec. 16.

19,603. P. Anchinachie. Distillation of aromatic waters, such as elder-flower water, rose-water, and the like. Dec. 9.

XXI.—PHOTOGRAPHY.**APPLICATIONS.**

25,980. J. Liddle.—From The International Photographic and Supply Company. Process of printing photographs on textile fabrics, and solutions connected therewith. Complete Specification. Nov. 18.

26,891. A. Hill and The Cresco-Fylma Company, Lim. A new or improved emulsion for photographic printing purposes. Nov. 26.

COMPLETE SPECIFICATION ACCEPTED.

1895.

22,138. A. Baumgarten. Coloured plates for photographic colour printing. Dec. 2.

XXII.—EXPLOSIVES, MATCHES, Etc.**APPLICATIONS.**

26,253. Vickers, Sons, and Co., Lim., A. T. Dawson, and G. T. Buckham. Improvements in primers for ordnance. Nov. 20.

26,334. T. A. Bayless and H. M. Smith. Improvements in or relating to the manufacture of primers or fuses in connection with cartridge cases, shells, and the like. Nov. 21.

26,819. T. Jenkins. Improvements in the charges of detonating railway fog-signals. Nov. 26.

27,197. A. Nobel. An improved manufacture of explosive compounds. Nov. 30.

27,684. L. Braly, L. Legat, A. Tachauer, and A. Delpey. An improved paste for the manufacture of matches. Dec. 4.

28,220. G. Beneke. Improved manufacture of explosives. Dec. 10.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

16,311. H. Maxim. Manufacture of smokeless explosives. Dec. 9.

16,862. H. Maxim. Manufacture of explosives and apparatus therefor. Dec. 16.

22,698. W. J. Orsman. Manufacture of explosives applicable for use in coal or other fiery mines. Dec. 2.

24,847. H. H. Lake.—From W. Greaves and E. M. Hann. Explosives. Dec. 2.

1896.

3023. H. H. Lake.—From Sprengstoff Actien Gesellschaft Carbonit. Method and apparatus for measuring the power or the volume of the gases resulting from the explosion of explosives. Dec. 16.

20,069. W. P. Thompson.—From La Société des Explosifs Industriels. Manufacture of explosives. Dec. 9.

XXIII.—ANALYTICAL CHEMISTRY.**COMPLETE SPECIFICATION ACCEPTED.**

1895.

22,303. G. Craig. A new or improved process for estimating the carbonic acid or other constituents in gases or products of combustion, and apparatus therefor. Nov. 25.
